Ethnocentrism and Prejudice: History of the Concepts

Boris Bizumic, ANU College of Medicine, Biology and Environment, The Australian National University, Canberra, ACT, Australia

Abstract

Ethnocentrism and prejudice are two distinct, though closely related, concepts. Since the early twentieth century, social scientists have tended to see them as fundamental social scientific concepts. This article presents a brief history of how social scientists conceptualized ethnocentrism and prejudice, and discusses their study with a focus on four prominent explanations that guided empirical research: (1) evolutionary, (2) threat and conflict, (3) self-aggrandizement, and (4) socialization and normative.

As phenomena, both ethnocentrism and prejudice have been observed and discussed since Ancient times. They became, however, fundamental social scientific concepts in the early twentieth century. Social scientists have widely studied both concepts, but they often meant different things to different researchers. This article will, therefore, first focus on the brief history of the two concepts and their varied, and often confusing, usages across disciplines. This will be followed with a history of explanations of ethnocentrism and prejudice, with a focus on four broad categories of explanations, which have been applied to both phenomena and which have guided empirical research. These theoretical approaches are (1) evolutionary, (2) threat and conflict, (3) self-aggrandizement, and (4) socialization and normative.

A Brief Conceptual History

It is very difficult to define ethnocentrism and prejudice. Conceptual analysis has rarely been applied to the two concepts. Neither concept has become clearer over time, and there is no universal agreement among social scientists on what ethnocentrism and prejudice mean. As a result, any discussion of these phenomena and their explanations is hindered due to vague, problematic, and inconsistent conceptualizations.

Ethnocentrism

The term 'ethnocentrism' combines the original Greek word 'ethnos' with the word 'center,' and its literal translation is that a particular 'ethnos' (ethnic group, nation, or people) is in the center. The concept has existed since at least the 1870s, and it was probably Ludwig Gumplowicz (born 9 March 1838; died 19/20 August 1909) who coined the concept (Gumplowicz, 1879, 1881), and used it in his books and papers written in German and Polish. William G. Sumner (born 30 October 1840; died 12 April 1910) later adopted and popularized the concept (Sumner, 1906). Given that Sumner did not reference Gumplowicz's work on ethnocentrism, later researchers (e.g., Adorno et al., 1950; LeVine and Campbell, 1972) have incorrectly credited Sumner with inventing the concept in 1906 (for the early conceptual history, see Bizumic, 2014).

Gumplowicz saw ethnocentrism as a similar concept to geocentrism and anthropocentrism, but with a focus on one's own ethnic group or people. He viewed it as a belief that one's own ethnic group is more important, superior, and better than any other group. Sumner similarly saw ethnocentrism as a "view of things in which one's own group is the center of everything, and all others are scaled and rated with reference to it" (Sumner, 1906: p. 13). He also included feelings of ingroup devotion and cohesion as well as rejection of outgroups, group superiority, and exploitative intergroup relations in his explicit conceptualizations of ethnocentrism (Sumner, 1906, 1911). Sumner, however, also assumed that ethnocentrism would almost always translate into outgroup negativity, and that ingroup positivity and outgroup negativity are highly intercorrelated.

Later social scientists based their conceptualizations of ethnocentrism on Sumner's writings, and given the complexity and breadth of his discussions of ethnocentrism, they tended to see it in various ways. Certain researchers have focused on intragroup factors, others on intergroup factors, and still others on outgroup factors. Occasionally, and influenced by the work of Theodor W. Adorno and colleagues (Adorno et al., 1950), ethnocentrism has been seen primarily as hostility or prejudice against a variety of outgroups. The influential book on theories of ethnocentrism by Robert LeVine and David Campbell focused on Sumner's conceptualizations and identified 23 facets in ethnocentrism, which they conceived as potentially a single dimension consisting of ingroup positivity and outgroup negativity (LeVine and Campbell, 1972). Empirical research, however, suggested that ingroup positivity (i.e., ingroup love) and outgroup negativity (i.e., outgroup hate) are often unrelated phenomena and not necessarily mutually interdependent (Brewer, 1999). Indeed, more recent cross-cultural measurement of ethnocentrism has suggested that there are two kinds of ethnocentrism: (1) intragroup ethnocentrism, which includes a sense of strong group cohesion and devotion to one's own ethnic group, and (2) intergroup ethnocentrism, which includes preference for ethnic ingroups over outgroups, a belief in ethnic superiority, a desire to maintain ethnic purity, and approval of exploitation of ethnic outgroups if it is in the interest of one's own ethnic group (Bizumic and Duckitt, 2012). These two kinds of ethnocentrism express a strong belief in the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03153-6

importance of one's own ethnic group and cover most historical definitions of ethnocentrism. These two kinds of ethnocentrism were shown to be empirically and conceptually distinct from mere ingroup positivity and outgroup negativity or prejudice.

Prejudice

The concept of prejudice itself is a much older concept than that of ethnocentrism. It comes from the Latin word 'praejudicium,' originally meaning 'prior judgment,' but over time acquiring the notion of generally unfavorable predetermined judgments. Prejudice has been a legal term for centuries, but isolated writings by social scientists on prejudice appeared in the nineteenth century. The concept, however, became popular in the social sciences only in the twentieth century when prejudice became a significant social and, by extension, social scientific problem. In fact, until the 1920s, social scientists did not consider prejudice as an important concept for research, and generally justified its existence, at least when the targets of prejudice were non-Western ethnic groups (Duckitt, 2010). This changed due to numerous societal reasons, and social scientists started to produce considerable work on prejudice, which they began seeing as a generally unjustified negative attitude toward a group of people, including every individual member.

Social scientists have broadly conceptualized prejudice as a negative attitudinal construct (Allport, 1954; Banton, 1998), although they have often focused on different kinds of negative attitudes, which at times overlapped with ethnocentrism (e.g., Adorno et al., 1950). Prejudice has often been seen as a negative attitude, based on an inaccurate and rigid generalization, toward a particular group or its group members (e.g., Allport, 1954). Many social scientists have argued that all kinds of prejudice are inaccurate, rigid, and unjustifiable. Others, however, have focused on a broader conceptualization. Indeed, the most important aspect of prejudice, on which most social scientists appear to agree, is that it includes a negative affect toward an outgroup, and this is reflected in both conceptual and empirical work. For example, Walter Stephan and Cookie Stephan (2000) saw and measured prejudice primarily as negative affect toward outgroups, involving both emotional reactions (e.g., hatred, disdain) and evaluations (e.g., disliking, disapproval) as well as the absence of positive emotions and evaluations. Social scientists have historically also distinguished between specific prejudice (negative attitude toward a specific group) and generalized prejudice (negative attitude that is generalized across many outgroups), which they often saw to be an aspect of ethnocentrism (Adorno et al., 1950). As mentioned above, however, research has shown that ethnocentric attitudes are conceptually and empirically distinct from prejudice (Bizumic and Duckitt, 2012; Brewer, 1999).

Ethnocentrism, Prejudice, and Social Groups

Since the beginning of the social scientific research into ethnocentrism and prejudice, most work has focused on ethnocultural and racial groups – even though both were at times related to any kind of social group. For example, despite the existence of 'ethno' in ethnocentrism, the concept was at times used to refer to diverse kinds of groups, including gender groups. Nevertheless, most social scientists see ethnocentrism as a characteristic of large-scale ethnocultural groups – though at times they also apply it to multiethnic nation states (e.g., US ethnocentrism) or even whole continents (e.g., European ethnocentrism). By definition, the concept of prejudice can be applied to any kind of social group, and social scientists at times have used it to refer to negative attitudes toward other species. Social scientists have, however, mainly used the concept to refer to prejudice against ethnocultural and racial groups, even though at times it was applied to women, religious groups, homosexuals, and other vulnerable or minority groups. Historically, both concepts have been predominantly studied among ethnic majority group members, whereas ethnic minorities and other vulnerable groups were often seen as recipients and targets of prejudiced attitudes, and their levels of ethnocentrism and prejudice have been largely unexplored.

A History of Explanations of Ethnocentrism and Prejudice

Social scientists have attempted to explain ethnocentrism and prejudice since the beginning of the social sciences, but the popularity and usefulness of various explanations have waxed and waned over time as well as across disciplines and across cultures. The influence of different theoretical explanations during particular periods has not been caused by the production of better theories or more convincing data in favor of certain explanations over others, but by a variety of external societal and political factors, which oriented social scientists toward different questions (Duckitt, 2010). In general, historical explanations have focused on the role of: (1) evolution, (2) threat and conflict, (3) self-aggrandizement, and (4) socialization and norms in the development of ethnocentrism and prejudice. These broad kinds of explanations have guided most of the social scientific research into ethnocentrism and prejudice.

Evolutionary Explanations

Evolutionary explanations of ethnocentrism and outgroup hostility are as old as the social sciences. In fact, the social sciences developed in part due to the Darwinian revolution in the nineteenth century when social phenomena, as extensions of natural phenomena, became legitimate scientific topics. It is not surprising, therefore, that many early theorists have attempted to explain ethnocentrism using an evolutionary framework. There is a wide range of evolutionary explanations, from Darwin's early theory and social Darwinist explanations to the more recent sociobiological and evolutionary psychological explanations. Ethnocentrism was explicitly related by Gumplowicz (1881) to anthropocentrism (giving humans the central place in the world), which evolutionary theory heavily criticized.

A common theme of evolutionary explanations is that humans are biologically hardwired to engage in both ethnocentrism and prejudice, and that ethnocentrism is evolutionarily useful because it enhances both individual and group

survival. Ethnocentrism and prejudice are, therefore, conceived as natural- and biology-based phenomena. Charles Darwin (born 12 February 1809; died 19 April 1882) wrote that in animals, "sympathy is directed solely toward the members of the same community, and therefore toward known, and more or less beloved members, but not to all the individuals of the same species" (Darwin, 1875: p. 106). Accordingly, humans, like other animals, also tend to engage in preferences toward members of their own community over others. Darwin also thought that intergroup competition makes people more cooperative with other members of their own group and that cooperative groups are more likely to thrive than noncooperative groups. Herbert Spencer (born 27 April 1820; died 8 December 1903), a social Darwinist, proposed two moral codes that exist universally in intragroup and intergroup relations (Spencer, 1892). He argued that one moral code approved of hostility toward those outside the group, whereas another code postulated that one should be highly cooperative with those inside one's own group. Spencer assumed that these exist among both industrial and nonindustrial societies. Sumner (1906), also a social Darwinist, elaborated upon the survival value of ethnocentrism, and assumed that outgroup hostility is a natural and normal correlate of ethnocentrism. Arthur Keith (1948), furthermore, argued that group survival is possible only if ingroup cooperation and intergroup competition are balanced, and that neither too much cooperation nor too much competition is good for groups. Although diverse, early explanations saw ethnocentrism and outgroup hostility as biology based and having survival value. Evolutionary theorists, however, frequently went beyond available data to claim that certain social groups are biologically superior and others are biologically inferior, and that it is right for the superior groups to rule over the inferior groups.

Although popular at the beginning of the twentieth century, evolutionary explanations became less influential from the 1930s until the 1970s. Anthropologists, sociologists, and psychologists began to produce strong evidence that brought into question many of the central assumptions of crude social Darwinism, such as the belief that there are inherent biological differences between different ethnic and racial groups. Anthropologists, in particular those who followed Franz Boas's (born 9 July 1858; died 22 December 1942) approach, have also advanced ideas of cultural relativism, which argued that cultures can only be understood from within and that cross-cultural comparisons (especially those advocating cultural superiority) are not useful and valid approaches for understanding and explaining human social behavior. Boas (1940) successfully questioned many crude biological and evolutionary applications to human groups and any inherent biological differences between members of different ethnic and racial groups. He also showed that many differences between ethnic and racial groups are better explained with environmental rather than biological factors. Finally, unrestrained ethnocentrism and prejudice, based on a naive evolutionary theorizing of social Darwinists, showed its extremely dark side during the 1930s and 1940s among the Nazis and fascists. Following the Second World War, evolutionary explanations of social phenomena, such as ethnocentrism and prejudice, have almost completely retreated.

Nevertheless, evolutionary explanations regained certain popularity again in the 1970s, and since then have been increasing in influence within academic circles. For example, social scientists used sociobiological theory to explain ethnocentrism. This theory proposes the concept of 'inclusive fitness,' which assumes that ingroup preferences are useful because genes could be passed to next generations not only from parents to their offspring but also through kin. Pierre van den Berghe (1978), for example, argued that both human and nonhuman animals prefer their kin over nonkin due to evolutionary reasons, and that altruism and self-sacrifice aimed at nonkin are not useful biologically. He assumed that humans tend to extend their kinship to the whole ethnic group, which is a unique kind of large-scale social group due to the existence (or, at least, a belief in the existence) of biological relatedness. This extension, therefore, tends to promote people's ethnocentric sacrifice and preference on behalf of their own group.

The past several decades have seen more evolutionary work on ethnocentrism and prejudice, including a focus on the role of explicit biological influences (e.g., genes and hormones), investigating ingroup preferences in other primates, and using simulation methodologies to test evolutionary underpinnings of ethnocentrism. The deterministic and crude evolutionary explanations characteristic of early social Darwinism have been supplemented with more sophisticated explanations. These explanations, however, often exaggerate the inevitability of ethnocentrism (though not necessarily outgroup prejudice) and minimize the role of social, cultural, and political factors.

Threat and Conflict Explanations

Many explanations of ethnocentrism and prejudice have focused on different kinds of threats and conflicts. These have ranged from realistic (e.g., economic) threats between groups to symbolic threats (e.g., threats stemming from perceiving different value or belief systems) and intrapsychic threats (e.g., psychodynamic threats and conflicts). A common theme in these theories is that ethnocentrism and prejudice are defensive reactions of individuals or groups against threats and conflicts.

Realistic conflict theory assumes that ethnocentric intragroup and intergroup attitudes as well as outgroup hostility are caused by realistic threats to the group and its welfare. Early sociologists were already concerned with the role of these threats in intergroup relations. For example, building on early realistic conflict theories of Gumplowicz and others, Sumner (1906) argued that ethnocentrism and outgroup hostility are functional in defending the ingroup against outgroup threats and advancing ingroup interests while in conflict with other groups. The work on realistic conflict theory and realistic threats became prominent in sociology and social psychology in the 1950s and 1960s. The theory was then elaborated upon and summarized by LeVine and Campbell (1972). This theory focuses on realistic threats to a group as opposed to unrealistic (i.e., psychodynamic, intrapsychic) threats and postulates that ethnocentrism and outgroup hostility are useful in helping groups defend against threat. It proposes that groups in conflict and under threat are more likely to defend themselves if they are ethnocentric and prejudiced. If, however, a group in conflict is accepting and considerate of outgroups

(i.e., nonethnocentric and nonprejudiced), it may risk being exploited or even destroyed.

Psychodynamic theorists, influenced by Sigmund Freud (born 6 May 1856; died 23 September 1939), however, assumed that ethnocentrism and prejudice are caused by intrapsychic threats and conflicts. Accordingly, these theorists have invoked a variety of defense mechanisms, which are thought to help individuals protect against these threats. This approach became particularly popular during the 1930s and 1940s because at that time, prejudice was being increasingly seen as irrational and unjustifiable (Duckitt, 2010). The most widely used defense mechanism to explain both ethnocentrism and prejudice was displacement. Freud (1930/1961), for example, argued that group life and ingroup cohesion are possible because people are able to displace their natural aggression and hostility onto outgroups.

The most influential psychodynamic theory of ethnocentrism and prejudice is authoritarian personality theory (Adorno et al., 1950). This theory posits that overly punitive and strict parenting causes an authoritarian personality, which is prone to ethnocentrism and generalized prejudice. Due to parental punitiveness and dependence on them, authoritarian people experience conflicting feelings, such as fear, love, and hostility. To cope with these ambivalent feelings, they employ defense mechanisms, such as repression, externalization, and displacement, which result in idealization of one's own group and prejudice against ethnic and other minority groups. For example, these authors wrote "the prejudiced subject's ambivalence toward his parents, with a repression and externalization of the negative side of this ambivalence, may be a factor in determining his strongly polarized attitudes, such as his uncritical acceptance of the ingroup and violent rejection of the outgroup" (Adorno et al., 1950: p. 482). Many later studies have supported the claim that authoritarianism is related to ethnocentrism and prejudice, but failed to support the psychodynamic explanation.

In contrast to other psychodynamic explanations, terror management theory has become influential in the 1990s and the 2000s. This theory builds on the work by Ernest Becker, and argues that the intrapsychic threat of mortality drives ethnocentric and prejudiced attitudes (Solomon et al., 1991). According to the theory, people are threatened by the awareness of eventual death and their cultural value systems serve as buffers against this existential anxiety. Any threat to one's own cultural system, therefore, makes people affirm their own cultural system and reject the systems of other groups. Indeed, research appears to indicate that ethnocentrism and prejudice may increase when people are reminded of their own mortality.

Psychologists and sociologists have proposed a wide range of other threats and conflicts to account for ethnocentrism and prejudice. For example, Milton Rokeach (1960) developed a belief congruence theory in the 1950s and 1960s. The theory argues that perceiving different beliefs and values in outgroup members, which conflict with one's own beliefs and values, might be sufficient to create group preferences and discrimination. According to the theory, people prefer those who have similar beliefs and values to themselves, and it is not ethnicity that causes ethnic preferences, but the perceived differences on important specific issues between those categorized as ethnic ingroup and outgroup members. Ethnic categorization is, therefore, important only as a symbol for "complexes of beliefs which to one degree or another are seen to be similar to and different from our own" (Rokeach, 1960: p. 391).

A later attempt was made to integrate different kinds of threats into broader theoretical frameworks. For example, integrated threat theory (Stephan and Stephan, 2000) proposed that in addition to realistic threats (i.e., threats to the general group welfare) and symbolic threats (i.e., threats to the values and beliefs of group members), there are two other threats as causes of prejudice: intergroup anxiety (i.e., irritation and fear caused by interpersonal interactions with members from another group) and negative stereotype threats (i.e., a negative perception of another group). A large body of research has indeed shown that both prejudice and ingroup, ethnocentric preferences increase as a result of these different threats (Riek et al., 2006).

Threat and conflict have been shown to have potent influences on ethnocentrism and prejudice. A variety of methodologies and approaches have shown that both ethnocentrism and prejudice tend to increase as a result of various threats. Nevertheless, social scientists have discovered that a certain amount of ethnocentrism may exist even in the absence of realistic conflicts and threats (Tajfel and Turner, 1979). Accordingly, it is still not clear whether threat and conflict could fully explain, or just exacerbate, already existing levels of ethnocentrism and prejudice. There are also endless examples from history of strong and threatening ethnic groups fully assimilating weaker ethnic groups. Threat may, therefore, at times create less, and not more, ethnocentrism and prejudice.

Self-Aggrandizement Explanations

A number of social scientists have explained ethnocentrism and prejudice as phenomena that make people feel good about themselves because they can increase people's sense of self-importance and esteem. Another group of explanations has assumed that these phenomena could be used to justify inequalities between different kinds of groups. These explanations refer to various self-aggrandizing functions of ethnocentrism and prejudice.

The potential to use ethnocentrism and prejudice to increase a person's self-esteem can be seen in Gumplowicz's description of ethnocentrism as a self-congratulatory delusion that ethnic groups employ, as well as in the psychodynamic links of narcissism with intergroup relations and prejudice (Freud, 1930/1961). Accordingly, ethnocentrism and prejudice might be easily seen as constructs that can make group members think and feel good about themselves. This explanation became particularly popular in the 1970s with the development of social identity theory by Henri Tajfel and John Turner (1979), which proposed that the need for positive self-esteem underlies ethnocentrism. Social identity research showed that ingroup bias in the lab (which Tajfel and Turner saw as an analog concept to ethnocentrism in the outside world) may exist even in artificially arranged minimal group situations. These situations are characterized by the absence of interaction between group members, the lack of knowledge about who ingroup or outgroup members are, as well as the absence of individual self-interest to discriminate. The only thing that people know in such situations is that

they are members of one group and not another. Still, numerous studies have shown that in these situations, people discriminate in favor of their ingroup over outgroups.

Social identity theory argued that when people categorize themselves into ingroups and other people into outgroups, they experience their self at a different level. As a result of a need for positive self-esteem (also called positive group distinctiveness), they want to feel good about their groups and they want their groups to be superior to other groups on relevant dimensions, and this need for positive self-esteem drives ethnocentric preferences. The theory has had a profound influence on various approaches that use categorization processes into ingroups and outgroups to explain intergroup relations and prejudice. Nevertheless, much subsequent work within this theoretical tradition has resulted in a variety of approaches that have tended to focus less on the motivational role of self-esteem and more on universal categorization processes, which in interaction with normative and socialization processes may reduce or increase ethnocentrism and prejudice.

A related group of self-aggrandizing approaches to ethnocentrism and prejudice has origins in Marxist and elite theories. Ethnocentrism and prejudice not only are useful in making people feel good about themselves but also may be useful in helping one group (usually the dominant group within a single society) exploit and rule over other groups. This approach, accordingly, claims that ethnocentrism and prejudice can be used by groups in order to exploit and dominate other groups for the sake of their own individual or group self-aggrandizement.

This approach came into widespread acceptance during 1960s and 1970s when numerous social movements of the 1960s led to an increase in the popularity of explanations based on Marxist theory (Banton, 1998). These explanations have focused on large-scale exploitative tendencies of dominant groups, which tend to use ethnocentrism and prejudice in order to promote their own selfish interests without consideration for the well-being of other groups. For example, Oliver C. Cox (1948) argued that prejudice is helpful in the dominance and exploitation of outgroups because it makes these outgroups appear inferior and deserving of exploitation. Cox, therefore, saw prejudice as an instrument of capitalism that helps the dominant group exploit subordinate groups, and he argued that relations between people of different racial groups represent relations between different social classes. Another example of this approach could be seen in the work of Teun A. van Dijk (1993), who used elite theory to argue that elites, including political, corporate, and academic elites, construct ethnocentric and prejudiced attitudes in various ways, and impose them on the rest of the population – including both ethnic minority and majority group members. His research using discourse analysis indeed suggested that ethnocentric and prejudiced attitudes are to a large extent constantly enforced by the elites (van Dijk, 1993).

A related theoretical framework, social dominance theory (Sidanius and Pratto, 1999), has focused on causes and consequences of social dominance orientation, which refers to individual differences in acceptance of hierarchical intergroup relations. This individual orientation appears to predispose people to support a wide variety of ideologies and attitudes, including ethnocentrism and prejudice, which give a differential value to social groups. Research indeed suggests that people's individual differences in their motivation for dominance and self-enhancement, together with individual differences in the motivation for security, appear to be the two main driving forces behind individual differences in ethnocentrism and prejudice (Duckitt, 2001).

Socialization and Normative Explanations

Social scientists have very frequently used socialization and norms to explain both ethnocentrism and prejudice. These explanations postulate that ethnocentrism and prejudice develop and persist in humans due to socialization in or conformity with ethnocentric and prejudiced social norms. The process of socialization usually involves internalization of social norms and other social influences.

Socialization and normative explanations gained prominence in the second half of the twentieth century. They were partly a reaction to individual difference explanations, such as authoritarian personality theory (Adorno et al., 1950). In an influential critique of personality explanations of prejudice, Thomas Pettigrew (1958) argued that normative influences are more important for the development of prejudice than internal psychological factors, such as authoritarian personality. For example, he showed that although Whites in the United States and South Africa tended to have similar scores on authoritarianism, South African Whites were more likely to show negative attitudes toward Blacks. Similarly, people in the South and North of the United States tended to have similar scores on authoritarianism, but the Southerners were more prejudiced against Blacks. Pettigrew, therefore, argued that prejudiced norms guide people's expressions of prejudice, and that they are much more important than individual differences. Similarly, Ralph Minard's (1952) research in the United States showed that Black and White miners conformed to dominant nonethnocentric norms of interaction and cooperation while at work, and to dominant ethnocentric norms of separation while they were in their communities. Studies such as these showed that socialization and social norms appear to have powerful influences on ethnocentrism and prejudice, and many subsequent approaches to reducing these phenomena focused on changing social norms.

Socialization and normative approaches have also been employed to interact with basic cognitive processes, such as social categorization, to explain ethnocentrism and prejudice. Social categorization approaches have, in general, postulated that categorization into groups is a basic precondition for ethnocentrism and prejudice (Allport, 1954). Although influenced by Allport's (1954) work, these theories have become particularly influential explanations of ethnocentrism and prejudice following the development of social identity theory in the late 1970s (Tajfel and Turner, 1979). They tended to show that how people categorize their social world has important implications for the development of ethnocentrism and prejudice. People tend to learn about social categories to which they belong and do not belong, the values associated with these social categories, and preferences for the social categories to which they belong over others. In fact,

ethnocentrism and prejudice are unlikely to exist if people failed to identify with certain social categories and disidentify with others. Given the general and universal processes of categorization, social categorization researchers have attempted to investigate what social conditions would foster or reduce prejudice and ethnocentrism. For example, social categorization researchers have argued that providing people with cross-cutting group categories might enable them to engage in less prejudice and ethnocentrism (Brewer, 1999).

Another group of explanations that focuses on socialization and norms of two different kinds of prejudice became popular in the 1980s and continues to capture the interest of social scientists until the current day (Crandall and Eshleman, 2005). These explanations propose two different kinds of prejudice. They suggest that as a result of different norms and social learning, people in Western societies have been developing different kinds of prejudiced attitudes. For example, due to egalitarian, nonethnocentric, and antiprejudiced norms, which are characteristic of many Western societies, new kinds of prejudice have been developing, which are replacing the traditional, blatant forms of prejudice. Although social scientists have used various terms for these kinds of prejudice (e.g., aversive, modern, symbolic, implicit, and subtle kinds of prejudice), what they have in common is that they are more subtle and sophisticated, but still predispose people to intergroup discrimination. This research has also suggested that people often may not even be aware that they are ethnocentric or prejudiced, but still have ethnocentric and prejudiced attitudes and act on them.

Despite a wide variety of socialization and normative theories, they do appear to share the same underlying emphasis on the role of external factors in shaping ethnocentrism and prejudice, and are therefore top–down theories, even though they may often interact with the more fundamental social cognitive processes. These theories assume that both ethnocentrism and prejudice could be transcended when socialization and social norms propagate humanitarian, nonprejudiced, and tolerant attitudes. Whether this is fully possible is an important question because socialization into any cultural world view appears to involve ethnocentrism, given that all cultures, at least at an implicit level, assume that one's own cultural norms, rules, and ethical systems are right and correct, and by extension, somewhat better than others.

Summary and Concluding Remarks

Social scientists from various disciplines have studied ethnocentrism and prejudice, and defined them in diverse ways, with ethnocentrism being primarily seen as a strong sense of intragroup and intergroup importance of one's own group, and prejudice as a negative, often unjustifiably negative, attitude toward an outgroup. Although sometimes used interchangeably, ethnocentrism and prejudice have been historically perceived as distinct, and research does support their conceptual and empirical distinction. Both have at times been used to refer to many kinds of groups, but most historical usages refer to large-scale ethnocultural groups in ethnocentrism and large-scale ethnocultural and racial groups in prejudice – although in the last several decades, there has been an increasing amount of research into prejudice against women, homosexuals, and other vulnerable groups.

Social scientists have approached ethnocentrism and prejudice from many angles, and these explanations could be categorized as those invoking: (1) evolutionary factors, (2) threat and conflict, (3) self-aggrandizement, and (4) socialization and norms. There is a wide variety of explanations within each of the categories, and some transcend even these broad categorizations. Nevertheless, it appears that social scientists have consistently drawn on these four broad kinds of explanations while trying to account for both ethnocentrism and prejudice.

Ethnocentrism and prejudice have appeared useful to researchers from different backgrounds and interests, and these concepts have been shown to be very fruitful and engaging. Unfortunately, conceptual clarity has not been of primary interest to the social scientists who have studied ethnocentrism and prejudice, and they have often failed to agree on right conceptualizations. Consequently, any summary of these wide areas of research needs to grapple with many conceptual issues and vague operationalizations. Both concepts have also been shown to be very difficult to change and eliminate, and their persistence still puzzles social scientists, especially those who reject evolutionary explanations. Any fruitful integrated approach to ethnocentrism and prejudice must, therefore, be able to address the four different kinds of explanations, which all have substantial bodies of supporting research, and shows how they independently, or in interaction with each other, produce ethnocentrism and prejudice.

Ethnogenesis in Anthropology

Abstract

Ethnogenesis is a process by which a distinct ethnic group emerges with a common sociocultural consciousness of belonging. The concept, coming on the anthropological studies in the 1960s, has been regenerated during the 1990s with new implications. It is used to focus on the interaction between global and local histories, especially on local initiatives to deal with the impact of globalization. Ethnogenesis therefore refers to cultural and political struggles by indigenous and enslaved populations to create enduring identities at times of often violently imposed radical change resulting from European domination. In the contemporary world system, they have begun to assert their sociocultural and politico-economic rights by reclaiming 'natural' sentiment of ethnicity. Ethnogenesis is thus becoming a key concept to diagnose and understand society in the twenty-first century.

Ethnogenesis is a process by which a distinct ethnic group emerges with a common sociocultural consciousness of belonging. In the 1960s Singer (1962) analyzed the process among African-Americans and Sturtevant (1971) subsequently introduced this term into the anthropological study of native Americans. Since then it has been widely utilized for examining the consciousness of belonging among various populations.

Although Sturtevant did no more than point out how ethnogenesis could be used to analyze the historical establishment of group distinctiveness, the concept has been regenerated during the 1990s with new implications. It is used to focus on the interaction between global and local histories, especially on local initiatives to deal with the impact of globalization. Ethnogenesis therefore refers to cultural and political struggles by indigenous and enslaved populations to create enduring identities at times of often violently imposed radical change resulting from European domination – such as demographic collapse, forced relocation, or enslavement. The idea of ethnogenesis refutes the established view of societies in the Third World as isolated, static, and ahistorical. Instead it pays attention to their creativity and ways of making history.

Theoretical Background

Currently the focus on issues of ethnicity has shifted from study of particular ethnic groups to looking at the dynamic process of ethnogenesis. This was made possible by the continued development of new theoretical understandings of ethnicity. Following Barth's contribution (1969), the subjective and interactive aspects of ethnicity began to gain attention. Despite the pre-eminence accorded the objective and primordial aspects of ethnicity by earlier perspectives, Barth did not regard ethnic identity as constituting an *a priori* reality, but as being an interactive process of self-definition and classification by others.

Actors categorize themselves and others in relation to how they interact with one another. It is when they use an ethnic identity to categorize themselves that Barth sees an ethnic group emerging. He rejected the prevailing idea that geographical and cultural isolation or separation is essential to the preservation of ethnic groups and the maintenance of cultural diversity. Instead he insisted that ethnic differentiation forms an overall social system; what is to be studied, consequently, is not the internal relations of the individual ethnic group, but the way the different ethnic groups establish boundaries. This perspective led to the view that ethnicity involved a formative process.

Another shift in the 1980s was the emergence of new perspectives that sought to deconstruct ethnicity as an essential entity. Deconstructionism in the social sciences exercised its influence to show how seemingly essential categories such as sex, generation, and race are far from being natural and *a priori*, but are an invention of modern society. Hobsbawm and Ranger showed that what had been taken to be traditional elements in symbols, customs, myths, and identity were actually invented as part of a dynamic process in the course of modern nation-building. According to this view, ethnic identity is also a modern invention that has been shaped in a political and historical way within the frame of the nation-state. This deconstructionist perspective, together with a subjective active view of ethnicity, provided a basis for the social sciences to theorize the phenomenon of ethnogenesis.

Ethnogenesis and Ethnocide

The concept of ethnogenesis has developed from studies of societies in the New World. Here the indigenous population was conquered and oppressed in the centuries after 1492. In addition, an enormous number of people with different cultural-linguistic backgrounds were transported from Africa and set to work as slaves. This is a process of ethnocide.

Ethnocide means the extermination of a culture. It involves the systematic destruction of cultural identities, ecosystems, political authorities, and religious rituals and belief systems. Common forms of ethnocide included the forced conversion to the religion of the colonizers, the banning of the use of native languages and cultural practices, and the forced relocation from the homeland to reservations.

Although it differs from genocide, which means the physical destruction of a whole people, the distinction is not always clear, and the two phenomena may occur together. Following the arrival of Columbus in the New World in 1492, the Arawak and Carib peoples he encountered, whose population is estimated to have numbered around 10 million, were almost entirely wiped out within 100 years. Virtually no indigenous people now remain in the Caribbean, although some were able to flee to the American continent where they merged with other survivors to generate new cultures.

In the century after the discovery, the indigenous population of South America, estimated to have been around 40 million, declined to about 440 000. In Australia in the nineteenth century the situation was much the same, although there were not as many people to be killed. The people of Tasmania, with an estimated population of 23 000 in 1803, were exterminated before the end of the century. Other people, on the verge of cultural extinction, have attempted to establish distinct cultural identities in order to reorganize their societies and secure their existence. This is a process of ethnogenesis. There is therefore a direct relationship between ethnocide and ethnogenesis. Where ethnocide takes place, one will usually also find ethnogenesis.

In the present day, peoples who were enslaved or marginalized under colonial domination are able to revive their cultural identities and reclaim their right to existence. This has gained momentum with the setting-up of statutory and voluntary organisations in the international context.

Mechanisms of Ethnogenesis

Minority populations which were marginalized in the world politico-economic system needed a shared consciousness of belonging. This required definitions of group boundaries, and processes of cultural creation, revitalization, and appropriation.

The creation of a religious ideology and practice was one means of integrating different groups into one unit. The enslaved African populations of the Caribbean, for instance, had originally come from a variety of sociocultural backgrounds with different languages, religions, value systems, and social structures. Despite these differences, they invented rituals, oaths, and a common set of religious values. This bricolage of different African elements became marked with the emergence of a Maroon identity in Jamaica in the middle of the seventeenth century.

In 1655, Britain took Jamaica from Spain by force. African slaves took advantage of the resulting turmoil to escape from the plantations into the forests and mountains. These deserters comprised a medley of ethnic origins, from Senegambia and the Gold Coast to the Congo and Angola, and even to the east coast of Africa. They were able to establish their own political authority and military alliances in the seventeenth and eighteenth centuries. Such polities created and mobilized common religious ideologies and practices based on rituals of spirit possession, which produced a shared consciousness and generated a common identity.

Ethnic identity may also be developed through a revitalization of precolonial symbols and ritual practices, as was the case with the Seminoles of Northern Florida. In the eighteenth century, when British, French, and Spanish forces were competing in the region, a distinct Seminole ethnicity emerged from the variety of Muskogean and other peoples with different cultural-linguistic backgrounds, who had colonized this region. They established new chiefdoms which closely followed the traditional Muskogee patterns. Among Muskogean peoples, who had previously been only loosely related with each other, there was the powerful division of Kawita, which overpowered the others and standardized and transformed a variety of politico-religious cultures under its hegemony. The early Seminole settlements still acknowledged Kawita's suzerainty. This meant giving a central role to rituals of the mythical creation of sacred fire, originally controlled by Kawita's traditional chiefs whose authority was thereby revitalized in the newly created Seminole societies.

Ethnogenesis may also take place through appropriation. From the late fifteenth century, indigenous peoples in the Third World were in most cases conquered by overwhelmingly superior European powers and forced to accept the religion, language, and way of living of the colonizers. In doing so, however, they often created a new ethnic identity by the way they transformed and adapted the ritual symbols of the Europeans. For instance, the Kapon and Makushi of Venezuela and Guyana emerged when the Christian saints and deities brought by the European colonizers were reinterpreted according to the traditional cosmology of indigenous peoples who used these ritual symbols to forge new cultural identities.

Ethnogenesis in the Twentieth Century

Although the process of ethnogenesis can be clearly seen in small-scale societies in the Third World following colonization, it has also developed in the process of modern nation-building. The ideology of the nation-state expressly aims to transform different ethnies into one nation with a single national culture. The principle is often different from the practice. The ruling group, in most cases the majority group but sometimes a numerical minority having dominant power, has generally monopolized the political-economic interests and imposed its culture on the others in the name of the national culture. In response, marginalized peoples have attempted to generate a new ethnic identity in order to claim their sociocultural and politico-economic rights within the frame of the nation-state. Modern ethnogenesis may be classified in three main ways.

The first type is integration. Those peoples who originally had formed separate and independent polities without any consciousness of belonging together were given the same name and treated as one group by European explorers, missionaries, anthropologists, and administrators. They accepted this name and formed a new identity in accordance with the imposed boundary, in order to resist or negotiate with the colonial regime, especially in modern nationalist movements that sought political independence. In the process, a new ethnicity emerged. This type of ethnogenesis can be seen among the Aborigines in Australia, the Inuit in the Arctic regions and the San in the Kalahari, where the central government has adopted policies of multiculturalism to secure minority group

rights – the government needs fixed sociocultural units in order to assist political autonomy and cultural preservation.

The second type is amalgamation, which occurred frequently in African societies at the time of independence. In Kenya after World War II, for example, an active African nationalism was organized by two major ethnic groups, the Kikuyu and the Luo. Political elites from smaller ethnic groups united under the hegemony of these two groups and gradually formed new cultural identities. Thus the Luyia emerged in the 1940s to bring together 17 Bantu-speaking peoples, among them the Maragoli, Bukusu, and the Wanga, who lived in what was then the North Kavirondo district of western Kenya. The word Luyia, meaning the communal space in which people sit around the fire, was appropriated for the the idea of mobilizing a consciousness of brotherhood among those from western Kenya who studied at Makerere University in Kampala.

The same sort of amalgamation took place among the 10 or so Eastern Cushitic-speaking ethnic groups in the Rift Valley. This ethnogenesis was promoted by those who studied at the prestigious Alliance high school in Nairobi in the 1940s. They invented the name of a new ethnic group, the Kalenjin – literal meaning 'I'm telling you' (in the plural sense) – and it started to spread among influential members of the home communities in the 1950s. Aidan Southall has termed this type of ethnogenesis 'supertribalization.'

The third type is separation. During the period of colonial domination, some small indigenous ethnic groups were subsumed into bigger neighboring groups or were put together in one large unit, either voluntarily or forcibly. Later they have attempted to revive their former cultural identity and secede from the constituted group, to create an independent ethnic group for themselves. The Suba, mainly living in the small islands of Lake Victoria, had been Luo-ized for a century, and their language was beginning to become extinct. But after the multiparty system was reintroduced into the Kenyan political scene in 1991, which caused the nation-state to become more ethnicized, the Suba political elite began to differentiate Suba from Luo and promoted the Suba culture and language. In so doing they are again forming themselves into a distinct ethnic group.

In the contemporary world system indigenous peoples and ethnic minorities who were once colonized and marginalized have begun to assert their socio-cultural and politico-economic rights. Because refashioned ethnic identities play a large part in such assertions, ethnogenesis is becoming a key concept in understanding society in the twenty-first century.

Abstract

Ethnography is the investigation and description of cultures and societies through fieldwork. Ethnographers conduct empirical research by immersing in local settings, establishing good rapport, and using qualitative methods such as participant observation and open interviews. This intersubjective construction of ethnographic knowledge requires close attention to forms of textual representation. The twentieth-century standard of long-term, face-to-face fieldwork has in the twenty-first century been broadened by multisited fieldwork and computer-mediated research.

The term ethnography refers to the first-hand study of people, cultures, and subjects in local settings, and to their description and analysis in written texts. Ethnography is as much the practice of investigation as the reporting of empirical findings. The investigator is on the one hand the research instrument that accesses reality through personal observations, experiences, and interactions, and on the other hand the author of ethnographic knowledge whose texts interpret the study object through different forms of argumentation and writing. The history of ethnography reflects its dual meaning as research and representation. Most key shifts and innovations analyzed here were pioneered by sociocultural anthropology, which continues to embrace ethnography with its experience-near data collection as the heart of the discipline. Sociology has made several important contributions, notably in urban studies, but has developed a growing preference for quantitative methods.

The historical antecedents of ethnography date back to classical antiquity in the writings of Herodotus and Tacitus about the Egyptians, Scythians, and Germanic tribes. They were travelers, like their medieval successors Marco Polo and the Muslim contemporary Ibn Battuta, who spent short periods at multiple locations and gathered knowledge through personal observations and local conversations (Launay, 2010). They developed a distinct genre of travel writing that reflected a sense of wonder at humankind's sociocultural variation, and added creative imaginations to contrast supposedly 'superior' civilizations with 'inferior' and 'primitive' cultures.

The rise of science and humanism during the Renaissance encouraged a more systematic study of non-Western cultures, an approach that had been predated in the fourteenth century by the Muslim historian Ibn Khaldun. The comparison of peoples and cultures called for scholarly reflection on universal classifications and proper research methods. The manual about data collection by French philosopher Joseph-Marie Degérando, written in 1800, was formative for ethnography. It served as the basis for the 1840 manual of the French Ethnological Society and the *Notes and Queries on Anthropology* of 1841 whose multiple editions were required reading for generations of British anthropologists (Urry, 1972).

Mid-nineteenth-century ethnographic studies by social scientists such as Morgan, Spencer, Tyler, and Frazer emphasized the classification of data according to evolutionary principles. For example, Lewis Henry Morgan (1985) discerned in his 1877 book *Ancient Society* stages of cultural evolution by comparing human societies in terms of subsistence, government, language, family types, religion, property, house life, and architecture. The sociocultural evolutionists were guided by a systematic data collection that distinguished their scientific reporting from contemporary travel accounts. Detailed ethnographic descriptions were presented according to general classes, categories, types, and taxonomies that facilitated cross-cultural comparison.

By the late-nineteenth century, ethnography underwent a major change when the quality of ethnographic data, the comparative method, and cultural evolution theory became questioned. Alfred Haddon's expedition to the Torres Straits islands presaged this change. First-hand empirical research was conducted by a multidisciplinary team of scientists that surveyed the archipelago as one cultural area, rejected speculative cross-cultural comparisons, and collected local classifications in the native language, although hardly observing their manifestation in people's everyday practices. Haddon introduced the term fieldwork into anthropology, and promulgated the merging of the armchair anthropologist with the field researcher into the ethnographer (Stocking, 1996). Franz Boas and Bronislaw Malinowski came to personify this ideal at the beginning of the twentieth century through their epistemological critiques of, respectively, anthropology's evolutionism and ethnographic methodology.

Founding Fathers of Ethnography: Boas and Malinowski

The German-American Franz Boas revolutionized ethnography in North America by emphasizing in-depth data collection and inductive analysis, while rejecting cultural evolution theory and the comparative method. He criticized the classifications of evolutionists as arbitrary, Eurocentric, and deduced from unsubstantiated laws and principles. Cultural phenomena that appeared similar were categorized erroneously into one class, even though their functions and meanings differed. The display of material culture in ethnographic museums demonstrated this misguided approach. Nineteenth-century museums decontextualized artifacts, such as bows and arrows, musical instruments, baskets, and clothing, by grouping them in separate display cases. Exhibitions were organized along the alleged

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12065-3

evolutionary development of material culture. Instead, Boas argued that different artifacts of one society should be grouped together as expressions of one cultural whole.

The understanding of cultures as integrated wholes, instead of manifestations of evolutionary stages, radically changed ethnographic practice and description. Data collection was no longer guided by preestablished classifications but by a holistic approach sensitive to the meanings, patterns, and internal consistency of sociocultural phenomena and traits within one culture. Still, Boas' writings demonstrate the vestiges of earlier styles of ethnography that clustered data in terms of analytical categories such as material culture, mythology, social organization, the arts, and rituals. Boas did not possess a thorough knowledge of local languages, and worked in partnership with a key informant who was taught how to present and translate local knowledge. These narratives were then reworked into native texts that erased their dialogical production and generated authoritative accounts (Briggs and Bauman, 1999). The lasting importance of Franz Boas to ethnography consists of his emphasis on the detailed description of cultures as integrated wholes, and his fundamental critique of the comparative method.

The Polish-British Bronislaw Malinowski (1984) carried ethnography forward by combining Boas' concern for rigorous data collection with experience-rich descriptions, and adding the importance of language fluency and the study of worldviews. Malinowski became the great synthesizer of ethnography, both as field-worker and author, and defined ethnography in terms of three objectives that required distinct methods and types of textual notation. One, the 'cultural anatomy' or 'firm skeleton of tribal life' must be delineated in a holistic manner as patterns and regularities. People act according to patterns unknown to them, so the field-worker must derive them from their behavior through observation and inductive inference. The field-worker records these regularities through systematic, quantitative documentation. Two, the 'flesh and blood' or 'imponderabilia of actual life' must be described by observing people's ordinary behavior and participating in their activities. The ethnographer's attention is not on the regularities of social life but on their individual enactment – including the field-worker's – and the subtle deviations from the patterns. These daily observations are recorded in an ethnographic diary. Finally, ethnography aims to study people's 'spirit,' 'subjective states,' or 'typical ways of thinking and feeling.' The ethnographer is not interested in people's psychology but in their verbalization of worldviews, opinions, and ideas as members of society. Speech is written down verbatim in the local tongue to constitute a corpus of native texts, very much like Boas had proposed.

Malinowski interpreted fieldwork as a dialectic of empathy and detachment, and turned participant observation into ethnography's key research method. Detachment enabled the delineation of rules and regularities embedded in thought and behavior through detailed observation. Empathy allowed the ethnographer to assume an insider's perspective through active participation in the local setting. The ethnographer's ultimate goal was 'to grasp the native's point of view' by drawing on the systematic documentation, the diary, and the native texts. Although other anthropologists had written ethnographies based on fieldwork, Malinowski most fully developed the research strategy under the influence of his intellectual mentor Rivers and his method of intensive study.

The author Malinowski (1984) made an effort to establish his ethnographic authority in his 1922 *Argonauts of the Western Pacific*. Occasionally, writing in the first pronoun and in the present tense, he described his lengthy residence among the Trobriand islanders, his isolation from 'white men' (Europeans), and his participation in ceremonies and rituals. Unlike Boas' neutral texts composed along distinct categories such as material culture and rituals, Malinowski's three ethnographies fuse his personal experiences with those of the Trobrianders to evoke the life cycles of ritual interisland exchanges, human reproduction, and agriculture. His studies combine a scientific stance, an experiential approach, and a narrative style that evokes lived experience (Payne, 1981).

Malinowski set the standard for ethnographic fieldwork in sociocultural anthropology with research in a local setting, conducted in the local language, data collection through participant observation, and inductive rather than deductive analysis. Similar developments were occurring in the United States, not only among the students of Boas but also especially among sociologists at the University of Chicago.

The Chicago School of Urban Sociology

During the 1920s and the 1930s, sociologists at the University of Chicago, influenced primarily by the work of American social psychologist George Herbert Mead, developed new forms of mostly urban-based ethnographic research, which became known as the 'Chicago School.' Led by Robert Park, Earnest Burgess, Herbert Blumer, William Thomas, Albion Small, Charles Horton Cooley, Florian Znaniecki, and Louis Wirth, the Chicago School represented the first major attempt to conduct systematic ethnographic fieldwork – particularly community studies – in urban environments beginning with Chicago but then spreading to other cities and to small town life and rural settings such as Jim Crow segregation in the south. Credited with institutionalizing, if not establishing, sociology as a modern science, Chicago School sociologists produced hundreds of monographs about topics such as Jewish ghettos and other ethnic quarters, taxi-dance halls, professional thieves, hobos, gangs, juvenile delinquents, labor strikers, and salesladies. They encouraged their students to do fieldwork, and reconceptualized their methodology around participant observation, which they referred to as a 'hands on' or 'getting one's hands dirty' method and which they opposed to 'armchair philosophy' based on library research.

Their research combined emerging theoretical approaches – mainly symbolic interactionism – with qualitative and quantitative methods of field research. Defining the city as a 'sociological laboratory,' many researchers lived in the community they studied for an extended period of time. They analyzed the everyday life and symbolic interactions characteristic of specific groups and communities, focused on social structures and environmental factors rather than genetic or individual personality characteristics, believed that the 'natural environment' a community inhabits is the main factor in shaping human behavior, and viewed the city as a microcosm: "In these great cities, where all the passions, all the energies of mankind are

released, we are in a position to investigate the process of civilization, as it were, under a microscope" (Park, 1928: p. 890).

The Chicago School ethnographers employed an 'ecological' approach (now called social ecology) to their studies, producing spot maps of cities identifying the location of specific behaviors such as alcoholism, homicide, suicide, psychoses, and poverty based on official data including census reports, housing and welfare records, and crime statistics, relating these data spatially to different neighborhoods. They employed multiple methods of triangulation and developed techniques of field research including interviewing, diaries, self-reported life histories, and case analyses to provide subjective balance to this quantitative and spatial analysis. They also identified and distinguished between 'patterns' (structures) and 'processes' (actions or behavior) as the constituting forces in society. They were eager to develop tools to not only research and understand society but also change or improve it, particularly by directing urban planning and social intervention agencies.

Chicago School ethnographers eschewed complex or abstract theoretical language and their approach was systematically influenced by Mead's ideas concerning the self, the other, social interaction, and the human capacity to be rational and take the role of the other. As Deegan observes, one of the fundamental theoretical foundations of Chicago School ethnography was Mead's understanding that "the scientific model of observation, data collection and interpretation is fundamentally a human project. Sociologists can learn to take the role of others because this is how all humans learn to become part of society" (2008: p. 19).

The New Ethnography

In the mid-1950s, an American school of thought emerged that called itself 'ethnoscience' or 'the New Ethnography.' Falling within the Boasian interest in cultural knowledge, the New Ethnography tried to develop a more rigorous ethnographic method than the rather intuitive, experiential approach of the Malinowskian tradition. Replication and reliability were the tests of validity. If ethnographers could reproduce the findings of previous field-workers, and could conduct themselves in culturally acceptable ways by using the ethnographic knowledge, then the research was considered valid.

Drawing on linguistic techniques such as componential analysis, ethnoscientists set out to isolate cultural classifications through structured interviews. The relations among contrasting conceptual categories were used to arrive at the cognitive model that determined people's thoughts and actions. The ethnographer should determine the boundaries of a cultural domain, such as a kinship system or a color system, and describe its internal structure or folk classification. A useful method to determine cultural classifications is through contrast sets. Informants are asked to contrast one kin term or color term with another. The answers are organized into taxonomies of mutually exclusive components that share only one culturally relevant feature, such as 'aunt' and 'uncle,' but not 'canoe' and 'uncle' (Sturtevant, 1964).

This research agenda posed the challenge of how to describe cognitive models. Recourse was taken again to linguistics, and in particular to Kenneth Pike's adaptation of vernacular and systematic descriptions of language to cultural phenomena. Pike coined the terms 'emic' and 'etic' in reference to the difference between phonemics and phonetics. The emic approach reproduces local terminologies, and constructs the cultural grammar underlying social behavior. The etic approach consists of the culture-free anthropological lexicon that allows the translation of local terms into generalizable knowledge. For example, 'aunt' is an emic term meaningful only in Anglo-American kinship terminology, while 'mother's sister' and 'father's sister' are the corresponding etic kinship terms. The emic approach should not be confused with Malinowski's native's point of view, which refers to people's experience of the world, not their cognition. The New Ethnography regarded the emic approach as an ethnographic method to map the tacit cultural logics, cognitive principles, and folk taxonomies that organize people's emotions, thoughts, and behavior (D'Andrade, 1995).

Contrary to its name, the New Ethnography hardly produced ethnographies but mostly articles on kinship and legal terminologies, color categories, and plant and animal taxonomies. A highlight of ethnoscience is the study *Basic Color Terms* by Berlin and Kay (1969). The authors compare the color lexicons of 98 languages and conclude that some societies distinguish as few as two colors but that there are 11 basic color categories: white, black, red, green, yellow, blue, brown, purple, pink, orange, and gray. Furthermore, all languages have at least black and white, and may then add additional colors along either one of two fixed temporal orders. Finally, the combined temporal order is evolutionary: color vocabularies with few color terms correlate with simple societies and simple technologies. Such decontextualized, evolutionary comparison seemed to defy the Boasian critique but demonstrated how decades of thorough *in situ* fieldwork had raised the quality of ethnographic data.

Criticism of the New Ethnography was raised with regard to its privileging of language over practice, the reduction of culture to cognition, the emphasis on the human mind, the neglect of intracultural variation, and the lack of attention to meaning. Ethnographic attention shifted during the 1970s from an emphasis on cultural classifications to symbolic meanings and local interpretations.

Thick Description and Reflexive Ethnography

The semiotic conceptualization of culture expounded by symbolic and interpretive anthropology revolutionized ethnography during the 1970s. Following the intellectual footsteps of German sociologist Max Weber, American anthropologist Clifford Geertz (1973) conceptualized culture as a web of meanings spun by the people themselves. Ethnography moved from its empiricist tendency toward hermeneutic interpretation. Fieldwork became like reading an old, partially faded manuscript with all the accompanying misreadings and mistranslations. Drawing on French philosopher Paul Ricoeur (1971), Geertz resembled cultures to documents as systems of meaning embodied in symbolic forms because of four similarities between cultural practices and texts: they are both meaningful; have observable objectifying consequences; supersede the original conditions,

relevance, and authorship of their production; and address different audiences.

Geertz defined ethnography as thick description. Thick description tried to unravel the conceptual structures and frames of local interpretation by studying people's conflicting social discourses in order to arrive at cultural systems of meaning. These systems are not emic analyses or descriptions of the actor's point of view but anthropological constructions of the actor's interpretations of his or her actions, emotions, beliefs, and experiences. The test of validity is ultimately the ethnography's imaginative quality. Textual representations take the form of detailed analyses of specific cultural phenomena as interpretations of larger sociocultural realities. Geertz's (1973) interpretation of cockfights in Bali is a typical study. He describes these events as social gatherings at which men gamble and play putting their prestige, masculinity, and social statuses at risk. The cockfight reveals the multiple fixed social hierarchies of Balinese society without ever changing them. It is therefore a metasocial commentary, a text about Balinese experience informing people about the lives they live.

The attention of interpretive anthropology to local meaning prompted the critique that the intersubjective construction of field data remained untouched. Reflexive anthropology arose in the 1980s to examine the narrative genres, forms, styles, structure, and rhetoric of ethnographic texts (Clifford and Marcus, 1986). This approach was strongly influenced by the practice theory of French sociologist Pierre Bourdieu, the study of discourses of power by French social philosopher Michel Foucault, and the dialogic theory of Russian philosopher Mikhail Bakhtin. Ethnographic research became interpreted as a practice of domination because of the unequal power relation between the authoritative fieldworker and the local informant.

Reflexive ethnography implies the study of the fieldworker's interpretive presuppositions and ethnographic authority, the interaction with research participants, the intercultural construction of ethnographic knowledge, and the narrative style of research findings. Ethnographers became conscious of how knowledge was produced in research and reporting, as exemplified by Paul Rabinow's (1977) analysis of his fieldwork in a Moroccan town. Intercultural translation by key informants required that they first understand their own culture before they could describe it to a foreign researcher who lacked any experiential knowledge of the culture under study. Moroccan interlocutors who were situated at the social periphery proved to be excellent interpreters because they could see across social boundaries.

In an era in which researched 'others' increasingly 'spoke back' to what was written about them, and with a heightened awareness of the relationship between power and the construction of knowledge, ethnographers sought to increase the voice of the 'other' through more active involvement of research participants. This was achieved by extensive use of direct quotes, coauthorship, reciprocity, collaboration, and partnership. Vincent Crapanzano (1980) addressed the intersubjective construction of cultural meaning in an exegesis of his research relation with the illiterate Moroccan tilemaker Tuhami. He reproduced the dialogic quality of fieldwork by presenting a literal transcription of distinct voices, questions and answers of Tuhami and himself, intermingled with anthropological commentary. Crapanzano chose an experimental writing style to convey this field encounter; other fieldworkers took an additional step toward ethnographic fiction and poetry.

Narrative Ethnography, Testimonio, and Ethnographic Fiction

The 1980s and 1990s saw the emergence of new forms of ethnographic writing, including narrative ethnography, *testimonio*, and ethnographic fiction. *Testimonio* or testimonial narrative was based on first-person accounts of situations involving violence, marginalization, or struggle for survival to bear witness to and denounce human rights abuses. Mostly emerging from Latin America, narratives such as the autobiographical *I, Rigoberta Menchú: An Indian Woman in Guatemala* (Menchú and Burgos-Debray, 1984) were intended to give a voice to the voiceless. *Testimonio* refers to a narrative in book form, told in the first person by a narrator who is a direct participant or witness of the events they recount, and is usually presented as a 'life story.' First and foremost, *testimonio* was intended to be a tactic of empowerment and survival in which the subaltern brought the existence of oppressive and repressive conditions to the world's attention in order to achieve social and political changes. It represented a form of experimental ethnography based on a new approach to fieldwork and a new relationship between the ethnographer and the 'other' (Beverly, 2004).

One of the most interesting developments in experimental forms of ethnographic writing has been the emergence of ethnographic fiction combining art and science. Ethnography and fiction have been juxtaposed in a number of theoretical areas, such as literary and postmodern interests in ethnography as a form of literature. Although ethnographic fiction has been criticized as inappropriate for consideration as ethnography, there has been a long tradition dating back to the nineteenth century of ethnographers writing fiction informed by fieldwork experiences (Narayan, 1999). There have been two main forms of juxtaposing ethnography with fiction, namely, fictional ethnography and ethnographic fiction, both of which aim to convey ethnographic realities. Fictional ethnography is written by trained ethnographers who write fictionalized accounts presented as 'real' ethnographies, whereas ethnographic fiction is usually written as novels or stories by writers who lack formal ethnographic training. Examples of the first include Elenore Smith Bowen (1964), Carlos Castaneda (1968), and Florinda Donner (1982); the second includes Susanna Kaysen (1990) and Mischa Berlinski (2008).

Both Castaneda's and Donner's books claim to be 'real' ethnographies by 'real' ethnographers, but have been revealed to essentially be ethnographically informed fiction or literature. Goldschmidt characterizes Castaneda's first books as "both ethnography and allegory," noting that it "demonstrates the essential skill of good ethnography – the capacity to enter into an alien world" (1968: pp. vii–viii). While Castaneda maintained that his experiences were real, his critics concluded that his five Don Juan books were a hoax (de Mille, 1980). Donner's book was also presented as a 'real' ethnographic account, but it too was revealed as fiction based on real ethnographic research.

Kaysen and Berlinski are not ethnographers. Their anthropological novels are based on extensive research and achieve what Bowen, Castaneda, and Donner are acclaimed for, conveying both ethnographic knowledge about 'other' peoples and cultures and evoking the complexities of the ethnographic encounter through fictionalized accounts.

While there is debate about whether this 'creative nonfiction' strays too far from fact into the realm of fiction, and about the ethics of injecting fictional inventions within works labeled 'ethnography,' Pratt (1986) and Narayan (1999) argue that ethnography has much to gain from writing outside established discursive traditions because the crossings between ethnography and fiction have been mutually enriching for both genres.

Engaged and Covert Ethnography

The first decade of this century has been marked by the contradictory emergence of 'engaged' and 'militarized' ethnography. The trends described above solidified into a politically engaged ethnography, which seeks to critically attract a wider readership and contribute to public debate about the urgent crises facing humankind today. Since its inception, social science was intended as an applied science. As a product of the European Enlightenment, it was based on the conviction that reason could and should be applied for the reduction of suffering and improvement of the human condition. In a contemporary reaffirmation of this vision, the core ethos and eidos of engaged ethnography is its ethical imperative to not only 'avoid harm' but to intentionally work to 'do some good' where it is needed. Engaged ethnography sees ethnographers as witnesses, instead of either dispassionate observers or political activists, who connect their readers to the world's trouble spots and sensitize them to the suffering and struggles of disprivileged human beings. It seeks to generate public discussion, influence opinion, and critically engage politicians and policymakers with the explicit goal of fostering genuine social change (Sanford and Angel-Ajani, 2006; Sluka and Robben, 2012).

Unfortunately, that all is not well with the epistemology of ethnography was revealed by the reemergence of covert mission-related counterinsurgency research by social scientists deployed by the US Army, which created renewed debate about the ethics, practice, and praxis of ethnographic fieldwork today. The goal of counterinsurgency research is population control and is viewed by the military as an element of 'combat power' – that is, as a weapon. Anthropologists first confronted the issue of militarized ethnography during the Vietnam War. This controversy led directly to the adoption of the first code of anthropological ethics in 1971, which effectively banned such research for over 30 years. However, in 2006, the US Army initiated a new experimental counterinsurgency program called the Human Terrain System, which began to embed social scientists with combat brigades in Iraq and Afghanistan to gather ethnographic intelligence. This generated renewed controversy among anthropologists, most of whom view it as fundamentally unethical, inherently harmful to those studied, and an attempt to 'weaponize' or 'recolonize' ethnography as an applied science of state control.

Militarized ethnography is a deceptive and unacceptable form of covert ethnographic research because legitimate consent cannot be given at the end of the barrel of a gun; the people studied are subjected to the research rather than willing participants in it; they are not informed of the real aims and agenda; confidentiality is not guaranteed; the data obtained are likely to be used to directly control, exploit, or harm them; and the findings are officially secret and will never be published or made available to them. Involvement of ethnographers in counterinsurgency research is not a form of engaged ethnography, as its practitioners pretend, but rather its antithesis because it contradicts the fundamental intention of engaged ethnography to function as a form of empowerment and resistance to imperialism, domination, and exploitation.

Conclusion

The accelerating globalization in the 1990s affected the Boasian-Malinowskian canon of fieldwork deeply. The idea of cultures as integrated wholes and their study through a personal immersion in one setting for the duration of 1 or 2 years became untenable. Research of hybrid cultures, global interconnections, translocal subjects, and new media demanded other ethnographic approaches. Multisited ethnography has been one strategy to examine the movements, paths, and connections among people, goods, and knowledge in different locations (Marcus, 1995; Hannerz, 2004). Field-workers make short trips to a patchwork of sites, collaborate with other field-workers, and skype with research participants. Netnography has emerged as the latest development in ethnography. Computer-mediated research of online communities and social media is combined with ethnographic fieldwork (Kozinets, 2010). Online interviews, Web text analyses, and Internet crowd surfing have not displaced participant observation and face-to-face interviews but are becoming important additional research methods. Ethnography thus continues to be a valuable strategy of research and representation that adapts to changing empirical circumstances.

Ethnography in Applied Social Research

David M Fetterman, San Jose, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Ethnography is the art and science of describing a group or culture. The ethnographer writes about the routine, daily lives of people. Fieldwork is the heart of the ethnographic research design. In the field, basic anthropological concepts, data collection methods and techniques, and analysis are the fundamental elements of 'doing ethnography.' Selection and use of various pieces of equipment – including the human instrument – facilitate the work. This process becomes product through analysis at various stages in ethnographic work – in field notes, memoranda, and interim reports, but most dramatically in the published report, article, or book.

Ethnography is the art and science of describing a group or culture. The description may be of a small tribal group in some exotic land or of a classroom in middle-class suburbia. The ethnographer writes about the routine, daily lives of people. The more predictable patterns of human thought and behavior are the focus of inquiry.

Ethnographers are noted for their ability to keep an open mind about the groups or cultures they are studying. However, this quality does not imply any lack of rigor. The ethnographer enters the field with an open mind, not an empty head. Before asking the first question in the field, the ethnographer begins with a problem, a theory or model, a research design, specific data collection techniques, tools for analysis, and a specific writing style. The ethnographer also begins with biases and preconceived notions about how people behave and what they think – as do researchers in every field. Indeed, the choice of what problem, geographic area, or people to study is in itself biased. Biases serve both positive and negative functions. Controlled, biases can focus and limit the research effort. Uncontrolled, they can undermine the quality of ethnographic research. To mitigate the negative effects of bias, the ethnographer must first make specific biases explicit. A series of additional quality controls, such as triangulation, contextualization, and a nonjudgmental orientation, place a check on the negative influence of bias.

An open mind also allows the ethnographer to explore rich, untapped sources of data not mapped out in the research design. The ethnographic study allows multiple interpretations of reality and alternative interpretations of data throughout the study. The ethnographer is interested in understanding and describing a social and cultural scene from the emic, or insider's perspective. The ethnographer is both storyteller and scientist; the closer the reader of ethnography comes to understanding the native's point of view, the better the story and the better the science.

Overview

Ethnographic work begins when the ethnographer selects a problem or topic and a theory or model to guide the study. The ethnographer simultaneously chooses whether to follow a basic or applied research approach to delineate and shape the effort. The research design then provides a basic set of instructions about what to do and where to go during the study. Fieldwork is the heart of the ethnographic research design. In the field, basic anthropological concepts, data collection methods and techniques, and analysis are the fundamental elements of 'doing ethnography.' Selection and use of various pieces of equipment – including the human instrument – facilitate the work. This process becomes product through analysis at various stages in ethnographic work – in field notes, memoranda, and interim reports, but most dramatically in the published report, article, or book.

This article provides a summary of the concepts, methods and techniques, equipment, analysis, writing, and ethics involved in ethnographic research. This approach highlights the utility of planning and organization in ethnographic work. The more organized the ethnographer, the easier his or her task of making sense of the mountains of data collected in the field. Sifting through notepads filled with illegible scrawl, listening to hours of digital voice recordings, labeling and organizing piles of digital photos, and cross-referencing data stored on hard drives or clouds are much less daunting to the ethnographer who has taken an organized, carefully planned approach.

The reality, however, is that ethnographic work is not always orderly. It involves serendipity, creativity, being in the right place at the right or wrong time, a lot of hard work, and old-fashioned luck. Thus, although this discussion proceeds within the confines of an orderly structure, I have made a concerted effort to ensure that it conveys as well the unplanned, sometimes chaotic, and always intriguing character of ethnographic research.

While in most research analysis follows data collection, in ethnographic research analysis and data collection begin simultaneously. An ethnographer is a human instrument and must discriminate among different types of data and analyze the relative worth of one path over another at every turn in fieldwork, well before any formalized analysis takes place. Clearly, ethnographic research involves all different levels of analysis. Analysis is an ongoing responsibility and joy from the first moment an ethnographer envisions a new project to the final stages of writing and reporting the findings.

Concepts

A few of the most important concepts that guide ethnographers in their fieldwork include culture, a holistic perspective, contextualization, emic perspective and multiple realities, etic perspective, and a nonjudgmental orientation.

Culture

Culture is the broadest ethnographic concept. Definitions of culture typically espouse either a materialist or an ideational perspective. The classic materialist interpretation of culture focuses on behavior. In this view, culture is the sum of a social group's observable patterns of behavior, customs, and way of life (see Harris, 1968: 16). The most popular ideational definition of culture is the cognitive definition. According to the cognitive approach, culture comprises the ideas, beliefs, and knowledge that characterize a particular group of people. This second definition specifically excludes behavior. Obviously, ethnographers need to know about both cultural behavior and cultural knowledge to describe a culture or subculture adequately. Although neither definition is sufficient, each offers the ethnographer a starting point and a perspective from which to approach the group under study.

Many anthropologists consider cultural interpretation ethnography's primary contribution. Cultural interpretation involves the researcher's ability to describe what he or she has heard and seen within the framework of the social group's view of reality. A classic example of the interpretive contribution involves the wink and the blink. A mechanical difference between the two may not be evident. However, the cultural context of each movement, the relationship between individuals that each act suggests, and the contexts surrounding the two help define and differentiate these two significantly different behaviors. Anyone who has ever mistaken a blink for a wink is fully aware of the significance of cultural interpretation for avoiding misunderstanding (see Fetterman, 1982: 24; Geertz, 1973: 6; Wolcott, 1980: 57, 59).

Holistic Perspective and Contextualization

Ethnographers assume a holistic outlook in research to gain a comprehensive and complete picture of a social group. Ethnographers attempt to describe as much as possible about a culture or a social group. This description might include the group's history, religion, politics, economy, and environment. No study can capture an entire culture or group. The holistic orientation forces the fieldworker to see beyond an immediate cultural scene or event in a classroom, hospital room, city street, or plush offices in Washington, D.C., New York, or Chicago. Each scene exists within a multilayered and interrelated context.

Contextualizing data involves placing observations into a larger perspective. For example, in one of my studies of an alternative high school for dropouts, it was important to describe the inner-city environment in which the schools were located – an impoverished neighborhood in which pimping, prostitution, arson for hire, rape, and murder were commonplace. This helped policy makers understand the power of certain elements in the community to distract students from their schoolwork. This description also provided some insight into the often lucrative alternatives with which the school competed in attracting and retaining students. Contextualization helped to provide a more accurate characterization of the school's degree of difficulty and helped to prevent a common error – blaming the victim (see also Fetterman, 1987a).

Emic and Etic Perspectives

The emic perspective – the insider's or native's perspective of reality – is at the heart of most ethnographic research. The insider's perception of reality is instrumental to understanding and accurately describing situations and behaviors. Native perceptions may not conform to an 'objective' reality, but they help the fieldworker understand why members of the social group do what they do. In contrast to a priori assumptions about how systems work from a simple, linear, logical perspective – which might be completely off target – ethnography typically takes a phenomenologically oriented research approach. An emic perspective compels the recognition and acceptance of multiple realities. Documenting multiple perspectives of reality in a given study is crucial to an understanding of why people think and act in the different ways they do. Differing perceptions of reality can be useful clues to individuals' religious, economic, or political status and can help a researcher understand maladaptive behavior patterns.

An etic perspective is an external, social scientific perspective on reality. Some ethnographers are interested only in describing the emic view, without placing their data in an etic or scientific perspective. They stand at the ideational and phenomenological end of the ethnographic spectrum. Other ethnographers prefer to rely on etically derived data first, and consider emically derived data secondary in their analysis. They stand at the materialist and positivist philosophical end of the ethnographic spectrum. Most ethnographers simply see emic and etic orientations as markers along a continuum of styles or different levels of analysis. Most ethnographers start collecting data from the emic perspective, then try to make sense of what they have collected in terms of both the native's view and their own scientific analysis. Just as thorough fieldwork requires an insightful and sensitive cultural interpretation combined with rigorous data-collection techniques, so good ethnography requires both emic and etic perspectives.

Nonjudgmental Orientation

A nonjudgmental orientation requires the ethnographer to suspend personal valuation of any given cultural practice. Maintaining a nonjudgmental orientation is similar to suspending disbelief while watching a movie or play, or reading a book – one accepts what may be an obviously illogical or unbelievable set of circumstances in order to allow the author to unravel a riveting story.

Concepts of culture, a holistic perspective, contextualization, emic perspective and multiple realities, etic perspective, and a nonjudgmental orientation place a check on our observations. They help the fieldworker see differences that may invalidate pat theories or hypotheses about observed events in the field. In some cases, these differences are systematic patterned activities for a broad spectrum of the community,

compelling the fieldworker to readjust the research focus; to throw away dated and inappropriate theories, models, hypotheses, and assumptions; and to modify the vision of the finished puzzle. In other cases, the differences are idiosyncratic but useful in underscoring another, dominant pattern – the exception that proves the rule. In most cases, however, such differences are instructive about a level or dimension of the community that had not received sufficient consideration (see Lavenda and Schultz, 2012 for additional discussion about concepts).

Methods and Techniques

The ethnographer is a human instrument. Ethnographic methods and techniques help to guide the ethnographer through the wilderness of personal observation and to identify and classify accurately the bewildering variety of events and actions that form a social situation.

Fieldwork

Fieldwork is the hallmark of research for both sociologists and anthropologists. The method is essentially the same for both types of researchers – working with people for long periods of time in their natural setting. The ethnographer conducts research in the native environment to see people and their behavior given all the real-world incentives and constraints. This naturalist approach avoids the artificial response typical of controlled or laboratory conditions. Understanding the world – or some small fragment of it – requires studying it in all its wonder and complexity. The task is in many ways more difficult than laboratory study, but it can also be more rewarding (see Mcall, 2006; Blommaert and Jie, 2011).

The fieldworker uses a variety of methods and techniques to ensure the integrity of the data. These methods and techniques objectify and standardize the researcher's perceptions. Of course, the ethnographer must adapt each one of the methods and techniques discussed below to the local environment. Resource constraints and deadlines may also limit the length of time for data gathering in the field – exploring, cross-checking, and recording information.

Selection, Sampling, and Entry

Research questions shape the selection of a place and a people or program to study. The ideal site for investigation of the research problem is not always accessible. In that event, the researcher accepts and notes the limitations of the study from the onset. Ideally, the focus of the investigation shifts to match the site under study.

The next step is to decide how to sample members of the target population. Most ethnographers use the big-net approach conducive to participant observation – mixing and mingling with everyone they can at first. As the study progresses, the focus narrows to specific portions of the population under study. The big-net approach ensures a wide-angle view of events before the microscopic study of specific interactions begins.

Ethnographers typically use informal strategies to begin fieldwork, such as starting wherever they can slip a foot in the door. (An introduction by a member is the ethnographer's best ticket into the community.) The most common technique is judgmental sampling; that is, ethnographers rely on their judgment to select the most appropriate members of the subculture or unit, based on the research question. Some experienced ethnographers use a rigorous randomized strategy to begin work – particularly when they already know a great deal about the culture or unit they are studying. However, using a highly structured randomized strategy without a basic understanding of the people under study may cause the researcher to narrow the focus prematurely, thus eliminating perhaps the very people or subjects relevant to the study.

Participant Observation

Participant observation characterizes most ethnographic research and is crucial to effective fieldwork. Participant observation combines participation in the lives of the people under study with maintenance of a professional distance that allows adequate observation and recording of data.

Participant observation is immersion in a culture. Ideally, the ethnographer lives and works in the community for 6 months to a year or more, learning the language and seeing patterns of behavior over time. Long-term residence helps the researcher internalize the basic beliefs, fears, hopes, and expectations of the people under study. The simple, ritualistic behaviors of going to the market or to the well for water teach how people use their time and space, how they determine what is precious, sacred, and profane. The process may seem unsystematic; in the beginning, it is somewhat uncontrolled and haphazard. However, even in the early stages of fieldwork the ethnographer searches out experiences and events as they come to his or her attention. Participant observation sets the stage for more refined techniques – including projective techniques and questionnaires – and becomes more refined itself as the fieldworker understands more and more about the culture. Ideas and behaviors that were only a blur to the ethnographer on entering the community take on a sharper focus. Participant observation can also help clarify the results of more refined instruments by providing a baseline of meaning and a way to reenter the field to explore the context for those (often unexpected) results.

In applied settings, participant observation is often noncontinuous, spread out over an extended time. Often the contract research budgets or time schedules of applied research do not allow long periods of study – continuous or noncontinuous. In these situations, the researcher can apply ethnographic techniques to the study, but cannot conduct ethnography.

Interviewing

The interview is the ethnographer's most important data-gathering technique. Interviews explain and put into a larger context what the ethnographer sees and experiences. General interview types include structured, semistructured, informal, and retrospective interviews.

Formally structured and semistructured interviews are verbal approximations of a questionnaire with explicit research goals. These interviews generally serve comparative and representative purposes – comparing responses and putting them in the context of common group beliefs and themes. A structured or semistructured interview is most valuable when the fieldworker comprehends the fundamentals of a community from the 'insider's' perspective. At this point, questions are more likely to conform to the native's perception of reality than to the researcher's.

Informal interviews are the most common form in ethnographic work. They seem to be casual conversations, but where structured interviews have an explicit agenda, informal interviews have a specific but implicit research agenda. The researcher uses informal approaches to discover the categories of meaning in a culture. Informal interviews are useful throughout an ethnographic study for discovering what people think and how one person's perceptions compare with another's. Such comparisons help the fieldworker to identify shared values in the community – values that inform behavior. Informal interviews are also useful for establishing and maintaining healthy rapport.

The ethnographer uses retrospective interviews to reconstruct the past, asking informants to recall personal historical information; retrospective interviews can be structured, semistructured, or informal. This type of interview does not elicit the most accurate data. People forget or filter past events. In some cases, retrospective interviews are the only way to gather information about the past. In situations where the ethnographer already has an accurate understanding of the historical facts, retrospective interviews provide useful information about individuals.

Key Actor or Informant Interviewing

Some people are more articulate and culturally sensitive than others. These individuals make excellent key actors or informants. In a social group under study, this individual is one of many actors, though they may not be a central or even an indispensable community member. Yet this individual becomes a key actor in the theater of ethnographic research and plays a pivotal role, linking the fieldworker and the community.

Key actors can provide detailed historical data, knowledge about contemporary interpersonal relationships (including conflicts), and a wealth of information about the nuances of everyday life. Although the ethnographer tries to speak with as many people as possible, time is always a factor. Therefore, anthropologists have traditionally relied most heavily on one or two individuals in a given group.

Key actors require careful selection. They are rarely perfect representatives of the group. However, they are usually members of the mainstream – otherwise, they would not have access to up-to-date cultural information. Key actors may be cultural brokers, straddling two cultures. This position may give them a special vantage point and objectivity about their culture. They may also be informal or formal leaders in the community. Key actors come from all walks of life and all socioeconomic and age groups.

The key actor and ethnographer must share a bond of trust. Respect on both sides is earned slowly. The ethnographer must take time to search out and spend time with these articulate individuals. The fieldworker learns to depend on the key actor's information – particularly as cross-checks with other sources prove it to be accurate and revealing. Ethnographers establish long-term relationships with key actors who continually provide reliable and insightful information. Key actors can be extremely effective and efficient sources of data and analysis.

At the same time, the ethnographer must judge the key actor's information cautiously. Overreliance on a key actor can be dangerous. Every study requires multiple sources. In addition, the fieldworker must take care to ensure that key actors do not simply provide answers they think the fieldworker wants to hear. The ethnographer can check answers rather easily, but must stay on guard against such distortion and contamination. Another, subtler problem occurs when a key actor begins to adopt the ethnographer's theoretical and conceptual framework. The key actor may inadvertently begin to describe the culture in terms of this a priori construct, undermining the fieldwork and distorting the emic or insider's perspective (for further discussion of the role of key informants, see Dobbert, 1982; Ellen, 1984; Freilick, 1970; Goetz and LeCompte, 1984; Pelto, 1970; Spradley, 1979; Taylor and Bogdan, 1984).

Questionnaires

Structured interviews are close approximations of questionnaires. Questionnaires represent perhaps the most formal and rigid form of exchange in the interviewing spectrum – the logical extension of an increasingly structured interview. However, questionnaires are qualitatively different from interviews because of the distance between the researcher and the respondent. Interviews have an interactive nature that questionnaires lack. In filling out a questionnaire, the respondent completes the researcher's form without any verbal exchange or clarification. Knowing whether the researcher and the respondent are on the same wavelength, sharing common assumptions and understandings about the questions, is difficult – perhaps impossible.

Misinterpretations and misrepresentations are common with questionnaires. Many people present idealized images of themselves on questionnaires, answering as they think they should to conform to a certain image. The researcher has no control over this type of response and no interpersonal cues to guide the interpretation of responses. Other problems include bias in the questions and poor return rates.

Despite these caveats, questionnaires are an excellent way for fieldworkers to tackle questions dealing with representativeness. They are the only realistic way of taking the pulses of hundreds or thousands of people. Anthropologists usually develop questionnaires to explore scientific concerns after they have a good grasp of how the larger pieces of the puzzle fit together. The questionnaire is a product of the ethnographer's knowledge about the system, and the researcher can adapt it to a specific topic or set of concerns. Ethnographers also use existing questionnaires to test hypotheses about specific conceptions and behaviors. However, the ethnographer must establish the relevance of a particular questionnaire to the target culture or subculture before administering it.

Online surveys and questionnaires provide an efficient way to document the views of large groups in a short period of time.

The questions are posted on the web, including yes/no, all that apply, open-ended, and five-point Likert scale questions. Respondents are notified about the location of the survey on the web (with a specific URL), enter their responses, and submit their survey online. The results are automatically calculated. The responses are often visually represented in a bar chart or similar graphic display as soon as the data are entered. This saves the ethnographer from the initial mailing costs, time-consuming and expensive postal reminders, and the expense of data entry concerning all the submitted surveys. Ethnographers can help computer-phobic respondents or those who do not have access to computer or the Internet complete the survey and enter their responses in the same online data base if necessary.

Projective Techniques

Projective techniques supplement and enhance fieldwork, they do not replace it. These techniques are employed by the ethnographer to elicit cultural and often psychological information from group members. Typically, the ethnographer holds an item up and asks the participant what it is. The researcher may have an idea about what the item represents, but that idea is less important than the participant's perception. The participant's responses usually reveal individual needs, fears, inclinations, and general worldview.

Project techniques, however revealing, rarely stand alone. The researcher needs to set these techniques in a larger research context to understand the elicited response completely. Projective techniques can elicit cues that can lead to further inquiry or can be one of several sources of information to support an ongoing hypothesis. Only the ethnographer's imagination limits the number of possible projective techniques. However, the fieldworker should use only those tests that can be relevant to the local group and the study.

Unobtrusive Measures

Most ethnographic methods are interactive: They involve dealing with people. A variety of other measures, however, does not require human interaction and can supplement interactive methods of data collection and analysis. These methods require only that the ethnographer keep eyes and ears open. Unobtrusive measures allow the ethnographer to draw social and cultural inferences from physical evidence (see Webb et al., 1966).

Outcroppings

Outcropping is a geological term referring to a portion of the bedrock that is visible on the surface – in other words, something that sticks out. Outcroppings in inner-city ethnographic research include skyscrapers, burned-out buildings, graffiti, the smell of urine on city streets, yards littered with garbage, a Rolls-Royce, or a syringe in the schoolyard. The researcher can quickly estimate the relative wealth or poverty of an area from these outcroppings. Initial inferences are possible without any human interaction. However, such cues by themselves can be misleading. A house with all the modern conveniences and luxuries imaginable can signal wealth, or can signal financial overextension verging on bankruptcy. The researcher must place each outcropping in a larger context. A broken syringe can have several meanings, depending on whether it lies on the floor of a doctor's office or in an elementary schoolyard late at night. On the walls of an inner-city school, the absence of graffiti is as important as its presence.

Changes in a physical setting over time can also be revealing. For example, an increase in the number of burned-out and empty buildings on a block indicates a decaying neighborhood. Conversely, an increase in the number of remodeled and revitalized houses may be indicative of gentrification, in which wealthy investors take over the neighborhood. The fieldworker must assess this abundant information with care, but should not ignore it or take it for granted.

Written and Electronic Information

In literate societies, written documents provide one of the most valuable and timesaving forms of data collection. In studies of office life, I have found past reports, memoranda, and personnel and payroll records invaluable. Mission statements and annual reports provide the organization's purpose or stated purpose and indicate the image the organization wishes to present to the outside world. Budgets tell a great deal about organizational values. Electronic mail is often less inhibited than general correspondence and thus quite revealing about office interrelationships, turf, and various power struggles. Proper use of this type of information can save the ethnographer's years of work.

Equipment

Notepads, computers, tape recorders, cameras – all the tools of ethnography are merely extensions of the human instrument, which aid to memory and vision. Yet these useful devices can facilitate the ethnographic mission by capturing the rich detail and flavor of the ethnographic experience and then helping to organize and analyze these data. Ethnographic equipment ranges from simple paper and pen to laptops and cloud storage, from digital recorders to digital cameras. The proper equipment can make the ethnographer's sojourn in an alien or unfamiliar culture more pleasant, safe, productive, and rewarding.

Analysis

Analysis is one of the most engaging features of ethnography. It begins at the moment a fieldworker selects a problem to study and ends with the last word in the report or ethnography. Ethnography involves many levels of analysis. Some are simple and informal; others require some statistical sophistication. Ethnographic analysis is iterative, building on ideas throughout the study. Analyzing data in the field enables the ethnographer to know precisely which methods to use next, as well as when and how to use them. Through analysis, the ethnographer tests hypotheses and perceptions to construct an accurate conceptual framework about what is happening in the social group under study. Analysis in ethnography is as much a test of the ethnographer as it is a test of the data.

Thinking

First and foremost, analysis is a test of the ethnographer's ability to think – to process information in a meaningful and useful manner. The ethnographer confronts a vast array of complex information and needs to make some sense of it all – piece by piece. The initial stage in analysis involves simple perception. However, even perception is selective. The ethnographer selects and isolates pieces of information from all the data in the field. The ethnographer's personal or idiosyncratic approach, together with an assortment of academic theories and models, focuses and limits the scope of inquiry. However, the field presents a vast amount of material, and in understanding day-to-day human interaction, elementary thinking skills such as those required for processing information are as important as ethnographic concepts and methods.

The ethnographer employs many useful techniques to make sense of the forests of data, from triangulation to the use of statistical software packages. All these techniques, however, require critical thinking skills – notably, the ability to synthesize and evaluate information – and a large dose of common sense.

Triangulation

Triangulation is basic in ethnographic research. It is at the heart of ethnographic validity, testing one source of information against another to strip away alternative explanations and prove a hypothesis. Typically, the ethnographer compares information sources to test the quality of the information (and the person sharing it), to understand more completely the part an actor plays in the social drama, and ultimately to put the whole situation into perspective (see Webb et al., 1966, for a detailed discussion of triangulation).

Patterns

Ethnographers look for patterns of thought and behavior. Patterns are a form of ethnographic reliability. Ethnographers see patterns of thought and action repeated in various situations and among various players. Looking for patterns is a form of analysis. The ethnographer begins with a mass of undifferentiated ideas and behavior, and then collects pieces of information, comparing, contrasting, and sorting gross categories and minutiae until a discernible thought or behavior becomes identifiable. Next the ethnographer must listen and observe, and then compare his or her observations with this poorly defined model. Exceptions to the rule emerge, variations on a theme are detectable. These variants help to circumscribe the activity and clarify its meaning. The process requires further sifting and sorting to make a match between categories. The theme or ritualistic activity finally emerges, consisting of a collection of such matches between the model (abstracted from reality) and the ongoing observed reality.

Any cultural group's patterns of thought and behavior are interwoven strands. As soon as the ethnographer finishes analyzing and identifying one pattern, another pattern emerges for analysis and identification. The fieldworker can then compare the two patterns. In practice, the ethnographer works simultaneously on many patterns. The level of understanding increases geometrically as the ethnographer moves up the conceptual ladder – mixing and matching patterns and building theory from the ground up (see Glaser and Strauss, 1967, for a discussion of grounded theory).

The observer can make preliminary inferences about the entire social system by analyzing the behavior that is subsumed within the pattern, as well as the patterns themselves. Ethnographers acquire a deeper understanding of and appreciation for a culture as they weave each part of the ornate human tapestry together, by observing and analyzing the patterns of everyday life.

Key Events

Key or focal events that the fieldworker can use to analyze an entire culture occur in every social group – Geertz (1973) eloquently used the cockfight to understand and portray Balinese life. Key events come in all shapes and sizes. Some tell more about a culture than others, but all provide a focus of analysis (see also Geertz, 1957).

Key events, like digital photographs or videos, concretely convey a wealth of information. Some images are clear representations of social activity; others provide a tremendous amount of embedded meaning. Once the event is recorded, the ethnographer can enlarge or reduce any portion of the picture. A rudimentary knowledge of the social situation will enable the ethnographer to infer a great deal from key events. In many cases, the event is a metaphor for a way of life or a specific social value. Key events provide lenses through which to view a culture.

Key events are extraordinarily useful for analysis. Not only do they help the fieldworker understand a social group, but the fieldworker in turn also can use them to explain the culture to others. The key event thus becomes a metaphor for the culture. Key events also illustrate how participation, observation, and analysis are inextricably bound together during fieldwork.

Content Analysis

Ethnographers analyze written and electronic data in much the same way they analyze observed behavior. They triangulate information within documents to test for internal consistency. They attempt to discover patterns within the text and seek key events recorded and memorialized in print.

Ethnographers may subject internal documents to special scrutiny to determine whether they are internally consistent with program philosophy. Reviews may also reveal significant patterns. It is often possible for the ethnographer to infer the significance of a concept from its frequency and context in the text (see Graneheim and Lundman, 2004; Neurendorf, 2001; Roberts, 1997; Stemler, 2001).

Statistics and Software

Ethnographers use nonparametric statistics more often than parametric statistics because they typically work with small samples. Parametric statistics require large samples for statistical significance. The use of nonparametric statistics is also more consistent with the needs and concerns of most anthropologists. An anthropologist typically works with nominal and

ordinal scales. Nominal scales consist of discrete categories, such as sex and religion. Ordinal scales also provide discrete categories as well as a range of variation within each category – for example, reform, conservative, and orthodox variants within the category of Judaism. Ordinal scales do not determine the degree of difference between subcategories. The Guttman (1944) scale also known as cumulative scaling or scalogram (Trochim, 2006a) analysis is one example of an ordinal scale that is useful in ethnographic research.

The chi-square test and the Fisher's exact probability test are popular nonparametric statistical tools in anthropology. However, all statistical formulas require that certain assumptions be met before the formulas may be applied to any situation. A disregard for these variables in the statistical equation is as dangerous as neglect of comparable assumptions in the human equation in conducting ethnographic fieldwork. Both errors result in distorted and misleading efforts at worst, and waste valuable time at best.

Ethnographers use parametric statistics when they have large samples and limited time and resources to conduct all the interviews. Survey and questionnaire work often requires sophisticated statistical tests of significance. T-tests are used to determine whether the means of two groups are statistically significant (Trochim, 2006b). Analysis of covariance design in regression analysis is another common test used when sample size permits in ethnography. Ethnographers also use the results of parametric statistics to test certain hypotheses, cross-check their own observations, and generally provide additional insight (see Fetterman, 2010, for discussion of problems with statistics).

There are many statistical software packages used to facilitate analysis ranging from Excel for descriptive statistics to SPSS. In addition, there are a number of software packages designed to facilitate qualitative data analysis, such as ATLAS.ti, MAXQDA, HyperResearch, and QDA.

Writing

Ethnography requires good writing skills at every stage of the enterprise. Research proposals, field notes, memoranda, interim reports, final reports, articles, and books are the tangible products of ethnographic work. The ethnographer can share these written works with participants to verify their accuracy and with colleagues for review and consideration. Ethnography offers many intangibles, through the media of participation and verbal communication. However, written products, unlike transitory conversations and interactions, withstand the test of time.

Writing good field notes is very different from writing a solid and illuminating ethnography or ethnographically informed report. Note taking is the rawest kind of writing. The note taker typically has an audience of one. Thus, although clarity, concision, and completeness are vital in note taking, style is not a primary consideration (see Emerson et al., 1995).

Writing for an audience, however, means writing to that audience. Reports for academics, government bureaucrats, private and public industry officials, medical professionals, and various educational program sponsors require different formats, languages, and levels of abstraction. The brevity and emphasis on findings in a report written for a program-level audience might raise some academics' eyebrows and cause them to question the project's intellectual effort. Similarly, a refereed scholarly publication would frustrate program personnel, who would likely feel that the researcher is wasting their time with irrelevant concerns, time that they need to take care of business. In essence, both parties feel that the researcher is simply not in touch with their reality. These two audiences are both interested in the fieldwork and the researcher's conclusions, but have different needs and concerns. Good ethnographic work can usually produce information that is relevant to both parties. (See Fetterman, 1987b, for discussion of the ethnographer as rhetorician. See also Yin, 1994, for discussion of differing audiences in the presentation of a case study.)

Writing is part of the analysis process as well as a means of communication (see also Hammersley and Atkinson, 1983). Writing clarifies thinking. In sitting down to put thoughts on paper, an individual must organize those thoughts and sort out specific ideas and relationships. Writing often reveals gaps in knowledge. If the researcher is still in the field when he or she discovers those gaps, the researcher needs to conduct additional interviews and observations of specific settings. If the researcher has left the field, field notes, e-mails, videoconference chats, and telephone calls must suffice (Fetterman, 1996). Embryonic ideas often come to maturity during writing, as the ethnographer crystallizes months of thought on a particular topic. From conception–as a twinkle in the ethnographer's eye – to delivery in the final report, an ethnographic study progresses through written stages. (For additional discussions of ethnographic writing, see Fetterman, 2010; Madison, 2005; Wolcott, 1990. See Van Maanen, 2011 for some of the rhetorical and narrative devices used in ethnographic work, including realist, confessional, and impressionist tales.)

Ethics

Ethnographers do not work in a vacuum, they work with people. They often pry into people's innermost secrets, sacred rites, achievements, and failures. In pursuing this personal science, ethnographers subscribe to a code of ethics that preserves the participants' rights, facilitates communication in the field, and leaves the door open for further research.

This code specifies first and foremost that the ethnographer do no harm to the people or the community under study. In seeking a logical path through the cultural wilds, the ethnographer is careful not to trample the feelings of natives or desecrate what the culture calls sacred. This respect for social environment ensures not only the rights of the people, but also the integrity of the data and a productive, enduring relationship between the people and the researcher. Professionalism and a delicate step demonstrate the ethnographer's deep respect, admiration, and appreciation for the people's way of life. Noninvasive ethnography is not only good ethics, but is also good science (see American Anthropological Association, 2012; Fetterman, 1983; Rynkiewich and Spradley, 1976; Weaver, 1973). Basic underlying ethical standards include the securing of permission (to protect individual privacy), honesty, trust (both implicit and explicit), and reciprocity.

Conclusion

This article highlighted the basic elements of ethnography. It included a discussion about concepts, methods and techniques, equipment, analysis, writing, and ethics. Step by step, this article provided a path through the complex terrain of ethnographic work.

Ethnohistory

Pauline T Strong, The University of Texas at Austin, Austin, TX, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Ethnohistory is an interdisciplinary approach to indigenous, colonial, and postcolonial culture and history. Combining the approaches of history, cultural anthropology, and archaeology, ethnohistory has most often focused on the cultures and histories of the indigenous peoples of settler societies in the Americas, Australia, New Zealand, the Pacific, and South Asia. Ethnohistory encompasses both particularistic and comparative scholarship and embodies productive tensions among historical, anthropological, and indigenous perspectives on cultural and historical processes.

Introduction

Ethnohistory is an interdisciplinary approach to indigenous, colonial, and postcolonial culture and history that developed as a coherent scholarly field in the United States in the 1950s. Combining the approaches of history, cultural anthropology, and archaeology, ethnohistory centers on reconstructing the history of non-European peoples, including their experiences of colonization and resistance. Ethnohistory began as an applied field, as historians and anthropologists collaborated on US tribal land claims cases, and it soon became institutionalized in an organization now known as the American Society for Ethnohistory (ASE). Ethnohistory expanded unevenly into other regional contexts, especially in South Asia and the Pacific, but the Americas has remained its center of gravity. Although there are programs in ethnohistory in university, museum, and governmental contexts, most ethnohistorians are trained primarily as anthropologists, historians, or archaeologists, such that ethnohistory remains an interdisciplinary pursuit rather than a discipline in itself.

There are strong connections between ethnohistory and other forms of interdisciplinary inquiry such as historical anthropology, historical archaeology, social history, oral history, subaltern studies, colonial studies, and indigenous studies, but ethnohistory is a fairly coherent scholarly formation that remains true to its particularistic and empirical roots. This article surveys the history of the field, some of its contributions to knowledge, and some of the ways in which ethnohistory has integrated and revealed tensions among historical, anthropological, and indigenous perspectives on cultural and historical processes. Such tensions have led to a productive reflexivity among some ethnohistorians.

The Development of Ethnohistory

Following the enactment in the United States of the Indian Claims Commission Act of 1946, anthropologists and historians were asked to serve as expert witnesses in court cases adjudicating tribal claims to territory. As legal historian Christian McMillen (2007) shows in *Making Indian Law: The Hualapai Land Case and the Birth of Ethnohistory*, this development was influenced by a landmark Supreme Court decision, *United States v. Santa Fe Pacific Railroad Company* (1941), that defined the basis of indigenous land claims as evidence of occupancy from 'time immemorial.' Conducting research for both sides (Indian tribes on the one hand and the Justice Department on the other), expert witnesses relied on colonial documents, oral histories, and ethnographic research to delineate indigenous concepts of rights to territory and resources; indigenous patterns of land use; indigenous and colonial understandings of treaty rights; the history of appropriation of land and resources from indigenous communities; and cultural continuities and discontinuities among indigenous populations. After 1978, when the Indian Claims Commission issued its final report, ethnohistorians continued to serve as expert witnesses in other contexts, including tribal recognition cases.

By 1978, however, ethnohistorians were conducting research that went well beyond the testimonial. The pursuit of ethnohistory consolidated a previously marginalized focus on Indian history within the field of history; in anthropology it brought a historical lens to culture change within indigenous cultures. The diachronic emphasis of ethnohistorical research provided a corrective to the synchronic nature of traditional ethnographic research, in which indigenous people were largely treated as static and timeless. Ethnography's focus on the 'ethnographic present' developed as a corrective to the speculative history of nineteenth-century historical evolutionism, but erroneously treated indigenous people as if they were 'without history,' in anthropologist Eric Wolf's (1982) memorable phrase. The neglect of history among anthropologists should not be overemphasized; however, the work of James Mooney on the Ghost Dance, published in the late nineteenth century, is an important exception to the rule. In the early twentieth century, John Swanton, Frank Speck, William Duncan Strong, Julian Steward, and William Fenton used historical methods in reconstructing indigenous culture; the latter became important in the development of ethnohistory. The acculturation studies carried out by Robert Redfield, Melville Herskovits, Robert Redfield, Oscar Lewis, and others in the 1930s also constituted a move toward understanding cultural change. In Britain, Evans-Pritchard's account of structural change among the Bedouins of Cyrenaica launched an interest in structural change and cultural conceptions of time that moved the discipline away from the synchronicity of structural functionalism.

Research on the politics, economics, ideologies, and social relations of what Georges Balandier called the 'colonial situation' (Cohn, 1980) became central to the development of

ethnohistory as a field. Ethnohistorians have productively analyzed the political economy of colonial empires, the impact of epidemics on indigenous populations, the nature of imperial bureaucracies, indigenous strategies of survival and resistance, and Christian evangelization and indigenous responses, among other topics. Studies of the gendered nature of the colonial situation, and especially changes in gender roles under colonialism and Christian evangelization, led to the development of feminist ethnohistory. Anthropologist Eleanor Leacock conducted important early work in this area, researching Innu (Naskapi) hunting territories and the impact of the fur trade on gender roles. In *Women and Colonization* (Etienne and Leacock, 1980), Leacock offered an historical materialist explanation of gender inequality that maintained that the allied forces of capitalism, colonialism, and Christianity led to the degradation of women's status among Native Americans, though not without resistance. Other studies inspired by Leacock have shown that the impact of capitalism and Christianity on gender roles has been extremely complex, varying according to indigenous gender relations as well as the manner in which indigenous economies articulated with the capitalist economy.

More recently what might be called the ethnohistory of sexuality has emerged in the work of scholars such as Ramón Gutierrez, Will Roscoe, and Ann Stoler interested in the dynamics of race, class, and sexuality in colonial systems of inequality. But this scholarship is associated less with ethnohistory than with an efflorescence of work in historical anthropology that emerged in the 1980s and 1990s. Historical anthropology, more a subfield of anthropology than an interdisciplinary field, is mainly outside the scope of this article (but *see* Anthropology and History).

The ASE, founded in 1954, awards the Erminie Wheeler-Voegelin Book Award annually to the author of the best book in the field. This award and the companion Robert F. Heizer Article Award offer an excellent way to keep abreast of developments in ethnohistory. The Society publishes the journal *Ethnohistory*; other venues in which ethnohistorical works frequently appear are *Comparative Studies in Society and History* and *History and Anthropology*. The ASE presidential address is published each year in *Ethnohistory* and often addresses current theoretical or methodological issues in the field.

Contributions to Knowledge

Ethnohistorians have compiled numerous collections of primary documents, including documents in indigenous languages, and cultural histories of particular indigenous peoples. These are important for providing fine-grained diachronic perspectives on indigenous experiences and perspectives. Of those ethnohistories that go beyond the particular to establish or exemplify significant strands of ethnohistorical scholarship, we will only be able to consider a representative sample.

One of the most influential ethnohistorical monographs ever published is anthropologist Anthony Wallace's *The Death and Rebirth of the Seneca*. In this ethnohistory Wallace draws on both archival and ethnographic research to reveal the development of the Handsome Lake religion among the Seneca Indians in the eighteenth century, which he analyzes as an example of a revitalization movement. This book has been a model for subsequent analyses of cultural revitalization, including *Reassessing Revitalization Movements: Perspectives from North America and the Pacific Islands*, edited by Michael Harkin. This collection looks comparatively at Pacific cargo cults, the Ghost Dance movement on the US Plains, and contemporary social movements, showing the comparative power and contemporary significance of Wallace's approach to cultural revitalization. Ethnohistorians have also looked at revitalization in the context of indigenous schools, cultural centers, language programs, and economic development efforts.

In the area of political economy the work of environmental historian Richard White has been particularly significant. Beginning with a monograph on the colonial production of political and economic dependency among the Choctaws, Pawnees, and Navajos, White has developed an approach to ethnohistory that focuses on changing modes of production, social relationships, and relationships to the environment. He and other scholars have chronicled the impact of the fur trade, farming, mining, and other European interventions on indigenous ecologies and economies, analyzing the forms of dependency and innovation that these interventions have engendered. Another approach to political economy is featured in *Captives and Cousins: Slavery, Kinship and Community in the Southwest Borderlands*, by historian James Brooks. This book analyzes the significance of indigenous forms of captivity, servitude, and adoption as forms of intercultural exchange and the significant changes to these patterns that occurred under colonialism.

Richard White is also known for the important concept of the 'middle ground.' First developed in *The Middle Ground: Indians, Empires, and Republics in the Great Lakes Region*, the concept refers to common patterns of social relationships and meaning that develop in situations of culture contact. Structural anthropologist Marshall Sahlins offers a somewhat similar concept, 'structures of the conjuncture,' in *Historical Metaphors and Mythical Realities: Structure in the Early History of the Sandwich Islands Kingdom*. While ethnohistorians trained in history, like White, are more likely to employ the more informal framework of 'the middle ground,' the approaches of Sahlins and White both offer ways of conceptualizing the hybrid social and cultural forms that develop in the course of intercultural encounters. Sahlins's earlier work on hunting and gathering economies has also been influential on ethnohistories like Robert Brightman's *Grateful Prey: Rock Cree Human-Animal Relationships*, that focus on indigenous economies and cultural logics. Like many anthropologists, Brightman is concerned with delineating the culturally specific concepts of the person that form a central part of indigenous cultural beliefs and practices.

Relations between indigenous peoples and the colonizing state have been a recurring concern of ethnohistory. Bringing the time depth of archaeology to the question, Bruce Trigger, Samuel Wilson, and others have shown that societies with higher degrees of political and economic integration tended to adapt more successfully to European conquest (Rogers and Wilson, 1993). In an extensive set of ethnohistorical works on India, anthropologist Bernard Cohn developed the concept of 'rule by records,' which has inspired numerous other important studies of colonial rule as a form of knowledge and power. Anthropologist Nicholas Dirks' *Castes of*

Mind: Colonialism and the Making of Modern India, for example, historicizes the notion of 'caste,' analyzing it neither as an essential cultural attribute nor as a colonial 'invention,' but as a complex product of indigenous culture, colonialism, and resistance.

One of the most productive arenas of ethnohistorical research is the study of colonial missions and indigenous responses. In *Ambivalent Conquests: Maya and Spaniard in Yucatan*, historian Inga Clendinnen considers missionary work and resistance among the Mayas in the Yucatan peninsula in the sixteenth century. Several influential accounts of conversion and resistance have been offered by anthropologists John and Jean Comaroff, including the latter's *Body of Power, Spirit of Resistance: The Culture and History of an African People*, which analyzes the Church of Zion among the Tshidi as a form of indigenous agency. Among the many studies of religious conversion, resistance, and syncretism in North America, anthropologist Edward Spicer's *Cycles of Conquest: The Impact of Spain, Mexico, and the United States on the Indians of the Southwest* stands out for its scope, while the many works of historian James Axtell are important for contrasting the conversion strategies of the French, English, and Iroquois. Anthropologist Sergei Kan has expanded the range of ethnohistorical comparison in his accounts of Tlingit religion and the impact of the Russian Orthodox Church.

Ethnohistorians have offered important contributions to the understanding of 'ethnogenesis,' or the formation of cultural groups through historical processes of culture contact and mixture. Studies of the Métis of Canada, the Seminoles of the US Southeast, the Garifuna of the Caribbean, and the Yoruba of Africa, among others, have employed this concept productively. *History, Power, and Identity: Ethnogenesis in the Americas*, a collection edited by anthropologist Thomas Hill, considers the development of new cultural identities among indigenous and African American groups, tying the emergence of new identities to global processes of domination, resistance, and exchange.

The linguistic anthropologist Michael Silverstein (1997) has called for, and demonstrated, an ethnohistory of communication, specifically, an ethnohistory of 'languages of encounter.' This ethnohistory concerns the reciprocal transformation of linguistic forms as well as the linguistic communities in which they are embedded. While Silverstein focuses on North America, his argument is relevant anywhere a 'contact community' has formed in which certain kinds of communication (pidginized forms used in trade or diplomacy, for example) occur among people who otherwise belong to distinct language communities. He emphasizes that the 'languages of encounter' used in trade or evangelization (Chinook Jargon, for example) differ significantly from the creole languages that developed on plantations. A monograph exemplifying the ethnohistory of communication, which is also an 'ethno-ethnohistorical' inquiry into indigenous conceptions of history, is *Understanding Tolowa Histories: Western Hegemonies and Native American Responses*, by linguistic anthropologist James Collins. Among other things, this book looks at the relationship between discourses of place and the expropriation of land.

Fortunately, ethnohistory has not been immune to the critique of ethnographic authority and the move to reflexive and collaborative scholarship that is characteristic of anthropology as a whole. An example of the new collaborative ethnohistory is *History is in the Land: Multivocal Tribal Traditions in Arizona's San Pedro Valley*, by archeologists Thomas Ferguson and John Colwell-Chanthaphonh. This ethnohistory is polyphonic, directly incorporating perspectives from representatives of the Tohono-O'odham, Hopi, Zuni, and San Carlos Apache tribal peoples. Reflexive scholarship in ethnohistory often concerns methodological issues, as discussed below, but there is also an important body of reflexive works on the representation of indigenous peoples. These include a critical examination of the role of history and anthropology in producing and circulating such representations. In *Land Filled With Flies: A Political Economy of the Kalahari*, anthropologist Edwin Wilmsen examines the ideological construction of the San (Bushmen) of southwestern Africa as 'primitive' rather than as a displaced and excluded underclass. Similarly, historian Jean O'Brien's *Firsting and Lasting: Writing Indians Out of Existence in New England* analyzes how local histories contributed to the discursive extinction of Indian peoples in New England, an extinction made familiar in the 'last of his tribe' trope. Coming full circle to the beginnings of ethnohistory, anthropologist Jack Campisi's *Tribe On Trial* reflects on his own experience as an expert witness in the Mashpee tribal recognition case, showing the problematic nature of the concept of 'tribe.'

Methodological Issues

A recurrent theme in ethnohistory has been the tension between the methodologies of anthropology and those of history, tensions aptly captured in historian Jennifer Brown's metaphor of 'strange bedfellows, kindred spirits.' Historians have tended to rely on the critical analysis of colonial documents, while anthropologists have put more credence in oral history, sometimes also 'upstreaming,' as William Fenton called it, from contemporary cultural practices to engage in informed speculation about the past. Anthropologists have also emphasized comparative analysis and indigenous conceptions of history, leading Raymond Fogelson to advocate for 'ethno-ethnohistory.'

As Fogelson's ironic reduplication suggests, there has been some tension over the name of the field itself. To what does the 'ethno' in 'ethnohistory' refer? For some scholars it refers substantively to indigenous and other ethnic groups, making ethnohistory the history of these groups. For others, it has methodological significance and refers to an ethnological or ethnographic approach to history. For still others, using an analogy to terms such as 'ethnobotany' or 'ethnoastronomy,' the name of the field refers to ethnic and indigenous groups' conceptions of their own pasts. All of these endeavors have taken place under the rubric of 'ethnohistory,' sometimes in the very same works. In light of these difficulties some scholars, especially those conducting research outside of the Americas, prefer to avoid the term altogether, referring instead to 'historical anthropology' or 'anthropological history.' Yet the term 'ethnohistory' persists, likely because a scholarly tradition and community has grown up around it and because it privileges one discipline less than the alternative terms.

Ethnohistorians typically rely on multiple forms of data, all of which must be utilized with considerable care. These include the following:

- Colonial and other institutional documents, including travel journals, missionary records, administrative records, judicial records, treaty records, memoirs, policy statements, and published narratives. In interpreting these primary documents the ethnohistorian must sort out (as much as possible) official categories, prejudices, and misapprehensions from indigenous beliefs and practices, putting the documents within the larger contexts of colonialism, capitalist expansion, evangelization, and indigenous and nationalist social movements. Like any historian, the ethnohistorian must also be aware of the selective and contingent nature of archiving (Galloway, 2006).
- Written records in indigenous languages. These are particularly significant for literate cultures, but may exist for oral cultures in translated form. They also may exist in written form for indigenous peoples like the Cherokee who developed a written form of their language after contact or those, like the Lakota, who learned to read and write in their native language from missionaries. Regarding his work with Euro-American and Lakota documents, Raymond DeMallie writes, "in a fundamental sense they represent conflicting realities, rooted in radically different epistemologies. The challenge of ethnohistory is to bring these two types of historical data together to construct a fuller picture of the past" (1993: 516).
- Archaeological evidence, which may offer a significantly longer diachronic dimension than historical and ethnographic evidence. Daniel Rogers and Samuel Wilson describe ethnohistorical and archaeological sources as 'complementary investigative routes' into postcontact cultural change (1993: 7), with archaeology particularly valuable for information on demography and geography, settlement and land use patterns, travel routes, and ethnic relationships.
- Collections, including maps, illustrations, photographs, and artifacts. Much ethnohistorical research occurs in museum collections, and these must be understood as subject to the same processes of selection, appropriation, misinterpretation, reinterpretation, and loss as historical archives (Galloway, 2006).
- Oral traditions, including oral histories, genealogies, folk tales, and place names. Like institutional documents, oral traditions must be contextualized within contemporary social structures and projects. As Africanist Jan Vansina has emphasized, oral traditions represent the viewpoints of particularly situated actors and may shift over time.
- Ethnographic research, including systematic participant observation, aimed at finding traces of, or attitudes toward, the past in the present. For some, ethnographic fieldwork is what differentiates the ethnohistorian from the conventional historian; for others, it is a more general 'anthropological orientation' toward culture (Cohn, 1968). In either case, the results of ethnographic research must always be understood as situated within a particular moment and particular ethnographic encounter. Ethnographic research produces its own archive, and ethnohistorians typically rely on the ethnographic research of previous generations as well as their own. A fine example of an ethnohistorian working through an ethnographic archive are Jennifer Brown's ethnohistorical works on the Berens River Ojibwa, using materials from A.I. Hallowell's fieldwork there in the 1930s.

Given this range of data, and the different forms of training that historians, anthropologists, and archeologists bring to the their research, it is not surprising that methodological issues arise frequently in the field of ethnohistory. Among these issues are:

- The problem of what Samuel Wilson calls 'mixed epistemologies,' with history, cultural anthropology, and archaeology each relying on different modes of explanation and validation. Wilson contrasts a neoevolutionary approach focused on long-term and large-scale processes with historical approaches more concerned with small-scale, shorter term processes. He compares this to the contrast Braudel draws between process-oriented history (the *longue durée*) and event-oriented history. This difference in scale poses "the challenge of integrating macroprocesses and microprocesses of culture change into a coherent analysis" (Rogers and Wilson, 1993: 21; 23).
- The contingency and partiality (in both senses) of documentary sources. Patricia Galloway (2006) notes the significance of material not noticed or not available to European observers; material misinterpreted by European observers; and material that has been lost. This situation requires a methodology of suspicion and convergence, in which documentary sources are viewed as compromised and explanations may be strengthened by the convergence of several lines of evidence, including archaeological, linguistic, and geographic evidence.
- The role of oral history, tribal history, and/or living memory as a supplement or corrective to written documents, which largely represent the perspective of colonial institutions. Jan Vansina (1985) has offered a methodology for the interpretation of oral history, including a way of distinguishing among ecological time, genealogical time, the sociological (recurring) calendar, and the time of extraordinary events. Anthropologists such as Julie Cruikshank have emphasized the importance of indigenous orientations to time, such as prophecy, that contrast sharply with linear time.
- The ability of ethnohistory to deal adequately with plural interpretations, including tensions or contradictions between (and within) archaeological, documentary, and oral histories. Historian Fred Hoxie has argued eloquently for an ethnohistory that aims "to describe community lives in their own terms," producing "stories that allow for an open vision—one that is coherent but attends to several layers of meaning and many co-existing interpretations" (1997: 606; 610). Anthropologist Raymond Fogelson agrees with this vision, while enumerating the difficulties posed to the ethnohistorian by "bi- or multicultural frames of reference …, by different modes of discourse, by documentation that cannot always be limited to written manuscripts, and by recognition of different conceptions of reality" (1989: 141).

- The role of theoretical concepts in the field, for example Michel Foucault's notion of bodily practice (as employed by Jean Comaroff, for instance), the structuralism of Marshall Sahlins, or Eric Wolf's use of world systems theory. Many ethnohistorians of a historical bent prefer highly particularistic analyses and express suspicion of the comparative analysis and theoretical framing characteristic of many of the ethnohistories produced by anthropologists. Fred Hoxie (1997), for example, counterposes the pluralistic ethnohistory he advocates to Eric Wolf's attempt, in *Europe and the People Without History*, to locate tribal histories within a global system. Many anthropologists, on the other hand, have lauded and tried to emulate Wolf's systematic vision.

Anthropologist Bernard Cohn (1980) offered a wise mediation between what he calls 'anthropologyland' and 'historyland,' noting that history and anthropology have a common subject matter, 'otherness'; a common project, translation; and a common interest in studying social transformation. He called for an 'anthropological history' in which the colonial situation is a privileged, unified analytic field for the study of the construction and representation of culture – indigenous culture, colonial culture, and postcolonial culture alike. Such an endeavor, he insisted, requires a working experience of both the field and the archive. This endeavor also needs to be highly reflexive, he insisted, and attuned to the ways in which current scholarly concepts are often remnants of colonial forms of rule. These include such basic concepts as 'culture,' 'race,' 'tribe,' and 'ethnic group.' Even the division between history and anthropology is a remnant of colonial notions of the timeless nature of 'primitive' people.

Emerging Directions in Ethnohistorical Research

In a provocative review of 'The State of Ethnohistory' Shepard Krech asked, "should ethnohistory cease to exist?" (1991: 346). Given the convergence or interpenetration of anthropological and historical methods since 1980 – in which scholars in both disciplines have been influenced by the Annales School of social history, world systems theory, the interpretive turn, and practice theory – is the field a legitimate one? Or does ethnohistory reproduce a colonialist practice in which 'history' refers to knowledge of the past in Western, literate societies, while 'ethnohistory' refers to all who are outside of that category? Was Eric Wolf correct in arguing that "The more ethnohistory we know, the more clearly 'their' history and 'our' history emerge as part of the same history" (19)?

The importance of this question has only increased in the decades since 1991 as the field of indigenous studies has grown in significance. Some argue that the conditions that gave rise to the interdisciplinary formation of ethnohistory have changed enough that it is no longer a viable field. Others, such as Jennifer Brown (1991), argue that ethnohistory has brought historians, anthropologists, archeologists, and indigenous people together in a fruitful enterprise that will always be changing but should not be scuttled.

Krech's position can be reversed, as Patricia Galloway (2006) does in *Practicing Ethnohistory: Mining Archives, Hearing Testimony, Constructing Narrative*. "If we are to go on practicing 'ethnohistory' at all," she writes, "and if by that we mean trying to write something we call history on the basis of incomplete and biased testimonies that we only partially understand, then we need to recognize that there is really no history that is *not* ethnohistory for a species whose daily personal communication is a clash of idiolects" (27). Perhaps the same argument can be made for anthropology: is there really no anthropology that is not ethnohistory for a species that lives in time?

The future of ethnohistory most likely lies between these two extremes. Ethnohistory will probably neither disappear nor subsume all of history, not in the foreseeable future anyway. It will likely continue to develop its strengths: being a 'middle ground,' as Brown (1991) puts it, between history and anthropology, between archive and field, between colonialist and indigenous perspectives. It will be strongest when practiced by scholars with experience in both the archive and the field, and when indigenous and nonindigenous scholars are collaborating side by side. It will be strongest when practiced by scholars with expertise in indigenous languages. It will be strongest when it is broadly comparative, and when local practices and meanings are tied to global processes and power relations. It will be strongest when multiple and sometimes conflicting, worldviews and perspectives are taken into account. And it will be strongest when it proceeds in a reflexive manner, subjecting its own practices to critique and revision. Such scholarship may not be called ethnohistory in the future, but it will reject the artificial, colonialist distinction between culture, prehistory, and history that is institutionalized in the academy's distinction between the fields of anthropology, archaeology, and history.

Ethnology

Gisela Welz, Goethe University, Frankfurt, Germany

© 2015 Elsevier Ltd. All rights reserved.

Abstract

In the historiography of the social sciences, ethnology is often taken to represent an early stage in the development of the anthropological disciplines. In the course of the twentieth century, ethnology was eclipsed by Social Cultural Anthropology. In many European countries, however, the term ethnology is used persistently. Here, a plethora of national ethnologies had evolved in the nineteenth century. Even today, this is reflected in the coexistence of divergent research programs and academic specializations called Ethnology. Addressing the historical transformation of ethnology allows us to reflect on the fact that scholarship in anthropology is far from homogeneous across national boundaries.

Ethnology started in the eighteenth century as a systematic attempt to acquire and compare information about the cultures of peoples and nations throughout the world. The first section of this chapter is dedicated to an understanding of Ethnology as a precursor of Cultural and Social Anthropology. However, transformations in the anthropological disciplines during the twentieth century led to a redefinition of ethnology as a specific approach within anthropology that is dedicated to cross-culturally comparative analyses. The second section of the chapter takes up this issue and discusses the historically contingent relationships among ethnology, ethnography, and anthropology. In many European countries, where national ethnologies evolved in the nineteenth century, there was a divergent development, which is briefly touched on in the third part of the chapter. The concluding section of the chapter addresses the role of ethnology within the context of global anthropologies in a postcolonial world.

Ethnology as the Formative Period of Anthropology

In the historiography of the social sciences, ethnology is taken to represent an early stage in the development of the anthropological disciplines. Academic circles at the German universities of Goettingen and Halle first used the term 'ethnology' in the late-eighteenth century. Coined as a derivation of the Greek word 'ethnos,' meaning 'a people,' the term 'ethnology' in its most general meaning indicates a scholarly interest in how aggregations of human beings are distinct from each other in terms of material culture, language, religion, moral ideas, or social institutions. Early developments in ethnology also included speculative theories about assumed interrelationships among the differences in cultural and biological groups. In the nineteenth century, ethnology had emerged as a line of inquiry into the culture history of humankind, initially supported and brought to public attention by the founding of learned societies and museums dedicated to ethnology in both Europe and the United States. This in turn prepared the ground for the inclusion of ethnology as an academic discipline in the curricula of universities, first in England, then in Germany and the United States.

In 1888, German-born natural scientist Franz Boas, who during the following decades would initiate and establish cultural anthropology as an academic discipline in the United States, lectured on 'The Aims of Ethnology' before an audience of well-educated German immigrants who were members of a civic society in New York City. He identified himself as an ethnologist and defined ethnology's agenda as follows: "The task of ethnology is the study of the total range of phenomena of social life. Language, customs, migrations, bodily characteristics are subjects of our studies. Thus its very first and most immediate object is the study of the history of mankind; not that of civilized nations alone, but that of the whole of mankind, from its earliest traces found in the deposits of the ice age, up to modern times" (Boas, 1948, 628).

Coming to ethnology in the late-nineteenth century, Boas found himself at the cusp of an important paradigm shift that changed the face of this still young discipline. Until this point, ethnology had been driven by the impetus to discover the hidden laws of human cultural development. Scholars hoped to do this by aggregating data about as many cultures as possible – both past and present – and by tabulating and classifying them. Findings were supplied by archaeology, itself an emerging discipline, or came from travel accounts, mission reports, and increasingly also from more sophisticated ethnographic surveys of indigenous groups in Africa, Asia, and the Americas. Most of the nineteenth century ethnologists attributed the manifestly observable cultural diversity of humankind to what they considered to be different levels of cultural development: The more 'primitive' groups were classified as being far down on the lowest rungs of the steep ladder of ascent to civilization. At the same time, these 'savages' personified, in the gaze of their more progressed contemporaries, the earliest evolutionary stages of humanity. Therefore, this approach, personified by, among others, Edward B. Tylor in England (1832–1917), Lewis Henry Morgan (1818–81) in America, and to some extent by Adolf Bastian (1826–1905) in Germany, was labeled – not by its protagonists, but by later opponents and historiographers – 'evolutionism.'

As increasingly more exact and detailed information about non-European cultures was made available, many evolutionist generalizations became untenable. At the turn of to the twentieth century and already anticipated by Boas in the lecture cited above, a new theory took over. It shifted the emphasis away from determining universal rules of cultural development; instead, evidence of migration and of contact between

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12066-5

groups and the resulting exchanges and transfers of cultural elements were then taken to be the key to the understanding of human history and cultural diversity. The underlying assumption was that human culture emerged from a single or a small number of origins, and the ensuing dispersal of cultural elements came about through migration and diffusion – hence the label of 'diffusionism' that was attributed to this new school. It had its strongest and methodologically innovative proponents among museum ethnologists such as Fritz Graebner (1877–1934) in Germany, who used similarities in the shapes and makeups of pottery vessels, weaponry, ornaments, and other artifacts as the bases to map geographical areas where cultures were assumed to have a shared origin. This enabled German-speaking ethnologists, among them Leo Frobenius (1873–1939) and Pater Wilhelm Schmidt (1868–1954), at the beginning of the twentieth century, to lay out a worldwide system of so-called Kulturkreise, areas of shared cultural traits. With their evolutionist predecessors, representatives of diffusionism shared a tendency toward sweeping generalizations and a disregard for the cultural meanings associated with the artifacts under scrutiny. They were not interested in the social integration of groups or in the cultural context of the customs they used as the bases for their theoretical speculations; rather, they treated them as isolates, much as if they were specimens of material culture in a collection's glass case. Also, while insisting that their endeavors were historical in nature, they established a frozen chronology of past cultures rather than dating events and gaining insights into historical processes.

Franz Boas (1858–1942), who had been trained by Bastian in Germany and was appointed a professor at Columbia University in New York City in 1899, rejected not only evolutionism – which had an American stronghold in the Smithsonian Institution's Bureau of American Ethnology in Washington DC – but German diffusionism as well. He founded a new approach, 'the historical method,' which could perhaps best be described as a moderate type of diffusionist ethnology. He and his students, however, shied away from projective theory and, indeed, from generalizations on a grand scale. They built up an enormous database from fieldwork among contemporary North American indigenous populations; their concept of culture areas paid careful attention to proven historical relationships among native American groups and also integrated environmental factors. With their emphasis on empirical research, the Boasians, students of Boas who became university professors in their own right at the most prestigious American universities, ended the era of speculative ethnology. In Great Britain, evolutionism proved to be more tenuous and was not superseded by diffusionist ideas until the 1920s.

Anthropology, Ethnology, Ethnography

In the late nineteenth and well into the twentieth century, anthropology became increasingly prevalent as an umbrella term to refer to a broad domain of scholarly interests in the biological, cognitive, and cultural dispositions of the human species, including physical anthropology, linguistics, and archaeology along with ethnology. In the course of these developments, ethnology was integrated as a subfield of the growing concern of anthropology. In the United States, the term ethnology continued to be used, but its meaning contracted to denote anthropological approaches that compared data concerning a number of groups or societies cross-culturally. Cross-cultural comparison had already been an indispensable tool for the historical reconstruction of cultural evolution as well as of cultural diffusion in the nineteenth century, both in the United States and in academic institutions in Europe, but it was not until the advent of the functionalist school that cross-cultural comparison had emerged as the principal methodology of British social anthropology. Relinquishing the generalizing thrust of earlier social anthropology, later approaches used comparison to inquire into the interplay of variable and invariable factors shaping social relations in a given culture by contrasting it with others like it, often in a controlled sample of regionally equivalent cultural groupings. Meanwhile, in the United States, the statistical analysis of nonmaterial cultural data had been further refined. The Human Relations Area Files at Yale University, a project that, since 1937, had abstracted and systematized the information on cultures around the world from ethnographic reports, developed into a huge cross-cultural data repository to be used for quantitative analyses and surveys.

By the end of World War II, the meaning of 'ethnology' had contracted to define but one of the three scholarly practices that form the anthropological enterprise. Ethnography was understood as data gathering in a single society, usually in a spatially and temporally bounded situation, such as when the fieldworker spends a year as a participant-observer in a local community and later writes up the findings in a stand-alone, case-study-type monograph (also called ethnography). Ethnology, by contrast, utilized the information collected in a number of ethnographies in order to engage in systematic cross-cultural comparisons between two or more societies. Ethnology in this sense was considered both distinct from and dependent on ethnography as the primary data gathering by fieldwork conducted in individual societies, but it also included, at times, information garnered from historical research. In a report on the status of anthropology in higher education submitted to UNESCO in 1954, French anthropologist Claude Lévi-Strauss defined ethnography, ethnology, and anthropology as three consecutive stages in the production of anthropological knowledge, each building up on the results of the other. Ethnology, to his mind, effected a synthesis by the systematic comparison of ethnographic data across cultures, but only anthropology, as the third and final stage, aspired to theory building with a generalizing impetus, attempting to come to universal statements about the nature of humanity (Lévi-Strauss, 1975).

In cultural anthropology in 1960s America, new developments predicated a significant shift away from comparative work. Most notably, Clifford Geertz's championing of 'thick description' suggested "not to generalize across cases but to generalize within them" (Geertz, 1973, 26) by in-depth immersion in one culture and ethnographic representation of one individual case study. During the 1980s, criticism of cross-cultural comparativism became increasingly vocal. In the second half of the twentieth century, many cultural anthropologists avoided cross-cultural perspectives altogether.

Instead, in-depth ethnographic accounts of particular cultural settings were considered the best reflection of anthropology's critical abilities within the concert of the humanities. In a contradictory movement, ethnography also was cast into doubt by a movement of textual critics and postcolonial historiographers of anthropology, but it emerged as the signature knowledge practice of cultural and social anthropology by the late-twentieth century.

Two important scholarly journals carry the designation 'ethnology' in their names: Ethnology, initiated by George Murdock in 1962, and the American Ethnologist, founded in 1972 at the suggestion of the American Anthropological Association 'to meet the growing demand to publish specifically socio-cultural anthropological articles' and also serving as the journal of the much older American Ethnological Society (founded in 1842). Indicative of the state of ethnology in English-language anthropology, these journals today present themselves to audiences and contributors as important venues for ethnographically produced findings in cultural and social anthropology. Ethnology is often taken today as an older and somewhat outdated synonym of cultural anthropology with which it shares the designation of study of present-day and recent cultures. Therefore, although ethnography as a mode of producing anthropological knowledge became unexpectedly central, especially in the United States and in those parts of the international arena where American-derived cultural anthropology is hegemonic, the term ethnology faded into the background. There were attempts to reassess comparative methodologies in anthropology, and new approaches were introduced to strengthen what is considered the inherently critical potential of comparison (see Gingrich and Fox, 2002), but 'ethnology' is no longer universally employed as a term to denote a specific approach in the production of anthropological knowledge. This may also have to do with the etymological connotations of the term 'ethnology' itself, because it contains the notion of 'ethnos,' of a bounded and homogeneous peoplehood as the basic unit of social life and of anthropological research. Many of the new research concerns of anthropology – migration and mobility, media and computer-mediated communication, statehood and supranational governance, commodities and consumption, science and technology – today entail a turning away from the idea of 'ethnos.' As a consequence of these transformations, anthropologists have abandoned established assumptions about how culture relates to territory. The primordialist notion of ethnos and the conventional culture concept of anthropology intimately bound up with it have been widely criticized, deconstructed, and abandoned.

The Multiplicity of Ethnologies in Europe

Today more than ever, Tomas Gerholm's and Ulf Hannerz's observation holds: "between different national and continental traditions as well as over time, there has been little consensus over the meaning of 'anthropology', 'ethnology' and 'ethnography'"(1982: 21). In Europe, the disciplinary landscape of anthropology is far from uniform. The names of academic disciplines, their boundaries, and their designated domains of scholarly inquiry differ from one country to the next, sometimes even among individual universities and research institutions. A closer look, however, reveals some remarkably consistent patterns. A split emerged in the nineteenth century, resulting in two separate anthropological disciplines coexisting in academic teaching and research.

On the one hand, national ethnologies emerged in individual countries, which "contributed to the cultural homogenization process of each nation" (Frykman, 2012, 578), embodied in the "the study of folklore and folk music, customs and costumes, housing and handicraft as they existed in peasant society" (Gerholm and Hannerz, 1982, 22). On the other hand, academic interest in the cultures of so-called primitive peoples and premodern peasant societies coalesced in the formation of research programs that during the twentieth century grew into a more general, often comparison-oriented anthropology. The names given to these two branches of the anthropological enterprise differed according to national languages from country to country. Because the bifurcation appears to have been articulated most strongly in the German-speaking countries, however, it has been labeled the 'Volkskunde/Voelkerkunde split' (Gerholm and Hannerz, 1982), even in English-language histories of the disciplines. Traditionally, the national ethnologies grouped under the Volkskunde heading were concerned with the historical investigation of and the cultural construction of a national heritage. Conversely, those disciplines belonging to the Voelkerkunde category focused on non-European 'primitive' peoples. The latter scholarly line of inquiry became dominant in societies marked by colonial expansionism, whereas the former interest led to the establishment of folklore and folklife studies dedicated to the philology and history of national and regional cultures in most of Eastern, Central, and Northern Europe. Although both "developed within the same traditions of cultural theory, and the early pioneers read much of the same classics, their position in academia came to be very different. European ethnology and folklore was defined as belonging to the humanities with links to history, literature, art history and language" (Loefgren, 2008, 119), whereas the comparative study of extra-European cultures was, more often than not, considered to be a social science. Since the 1960s, both sections of the anthropological enterprise in continental Europe have undergone marked modernization, in some countries leading to a rapprochement of the disciplines. The designation of European Ethnology had originally been invented in 1955 at a conference in Arnhem, during one of the first postwar encounters of scholars from various European countries. Those who championed this designation wanted it to be strongly inclusive of the differing orientations of national ethnologies and folklore studies by emphasizing a common European perspective. The 1964 founding of the International Society of Ethnology and Folklore initially emphasized differences rather than commonalities. Through the years it has proven to function as a Europe-wide organization of scholars who do research in Europe within the context of national ethnologies and their modernized successor disciplines. The Europe-wide journal 'Ethnologia Europaea' also grew from the concern with European ethnology that was most pronounced in the Scandinavian countries. There, ethnology originally was a museum-based research program concerned with the material culture of non-European, small-scale societies. However, it had transformed

itself into an internationally acclaimed social anthropology by the 1970s. The label ethnology was then appropriated by the successors of national folklore studies and prefixed with 'European.' "As European ethnologists in the 1960s oriented their research towards modern industrial society rather than the vanishing peasant traditions, the basic concept of folk culture was exchanged for the study of the everyday and 'the ordinary people'"(Loefgren, 2008, 126). The popular culture, cultural creativity, and consumption as a symbolically expressive practice took the place of tradition, customs, and heritage on the disciplinary agenda.

In the German-speaking countries of Europe, the national ethnologies had, after World War II, initially rejected the new label of European Ethnology, continuing to identify themselves instead as Volkskunde. During the modernization process of the disciplines in the 1970s, the term ethnology was adopted by Voelkerkunde (Haller, 2012), while many university departments and programs previously called Volkskunde acquired new names, such as cultural studies, empirical cultural research, European ethnology, and cultural anthropology. Their name changes signified a shift toward the problem-oriented study of contemporary German, Swiss, or Austrian society informed by new developments in social thought, especially the critical theory of the Frankfurt School, but also with advances in social research (Bausinger, 1986). In addition, early British cultural studies of the Birmingham school proved a strong inspiration for the new focus on everyday life, consumption, and expressive cultures (Warneken, 2006). In Germany, the striving for a new rationale for the discipline had been animated by the need to come clear of any associations with the Nazi past that had haunted the discipline since the end of World War II. The rejection of the old Volkskunde designation signaled a theoretical paradigm shift as much it did a political turning point, leaving behind the politically conservative, often at least latently nationalist, research agenda (Bendix, 1997).

In many other European countries, even those not characterized by a marked split between ethnologists working abroad and those working in their own societies, an anthropological turn could be observed by the 1980s, aligning academic programs and research orientations more closely with Anglo-American cultural and social anthropology. An exception is France, where 'ethnologie' continues to be a term valid for both the intra- and extra-European research endeavors conducted by anthropologists (see Segalen, 2008). There, since the 1970s, the Ethnologie Contemporaine de la France represented a new orientation of anthropological inquiry into French society with a strong ethnographic flavor. Its focus on urban and rural communities is not unlike the research interest that a group of social anthropologists and sociologists in the United Kingdom started to pursue under the heading of Anthropology of Britain, generating community studies that were acclaimed as important case studies of social change in twentieth-century England, Scotland, and Wales (see Macdonald et al., 2005).

In Eastern European countries, before the transition of 1989, the division of labor among disciplines had been organized according to the Marxian classification of academic endeavors. The discipline was often called ethnography, rather than ethnology, and was considered an auxiliary to history. Ethnography in the socialist countries, however, had sometimes included scholars working both within and outside of Europe. Yet the flavor of ethnology in many countries was strongly nationalist, its research celebratory of working-class and rural folk cultures. Even after the post-1989 transformations, the "traditional canon of Volkskunde lingered on longer in East and Central Europe" (Kiliánová, 2012, 104) than it had in Germany and the Scandinavian countries, leading the Polish anthropologist Michal Buchowski to demand, even in 2012, that "the myth of nationalist ethnology in (post)socialist Central and East Europe must be dispelled" (Buchowski, 2012, 68). In many Eastern European countries, however, the homegrown national ethnologies and ethnographic research programs were resolutely 'anthropologized' (Rihtman-Augustin and Capo Zmegac, 2004), adopting an orientation toward American cultural anthropology and/or the British-derived social anthropology.

Today, social anthropologists claim to be the most visible and numerous group of anthropologists in Europe. In 1989, the European Association of Social Anthropologists (EASA) was conceived by its founders as a counterbalance to the American hegemony in anthropology. It has evolved into one of the main arenas for young scholars working in the interface of ethnology, anthropology, and sociology, many of them focusing on contemporary European societies rather than on non-European field sites.

Many of the contributors to EASA's events and publication series come from southern Europe. There, new departments of anthropology have emerged, and they combine research interests in their home countries with the most advanced theoretical developments in international anthropology. In Spain, Portugal, and Greece, nationalist ethnologies and folklore studies were successfully superceded and discarded in favor of a social-science-oriented anthropology that tackles problems of contemporary Mediterranean societies, such as urban growth, social change, and immigration. Southern European anthropologists have also entered into a productive dialogue with an older Europeanist specialization that had developed in American cultural anthropology and British social anthropology. In the 1970s, Anglo-American social and cultural anthropologists had already conducted community studies in Mediterranean countries (Boissevain, 1994).

A Future for Ethnology?

Historically, ethnology is a Europe-derived academic project. In many European countries, ethnology not only continues to be widely used as a disciplinary designation, but also the term has been adopted, and even reinvented, to suggest new directions taken in the anthropological investigation of contemporary European societies. European ethnologies today, however, constitute a minor academic tradition within the broader arena of global anthropologies. The majority of their publications are not in English but in their respective countries' languages. As a consequence, they have less visibility than those of their colleagues who participate in English-language dominated, transnational discourse. Meanwhile, most markedly in the United States but also in other Anglo-Saxon countries, ethnology has receded and been eclipsed by anthropology. The impact of this development extends into other countries whose

academic institutions employ anthropologists who have acquired their academic training and university degrees in North American or British universities or at institutions of learning influenced by them. Yet the beginning of the twenty-first century also sees anthropological studies in new nations on the rise, such as Brazil, Mexico, and India, for some of whom the ethnological tradition of inquiry into the cultures of indigenous groups is a problematic legacy of the colonial past but one that they have long since left behind and instead, have successfully developed their own anthropological institutions, theoretical discourses, and research agendas (Lins Ribeiro and Escobar, 2006). These postcolonial anthropologies of the global south, for the most part, have no stake in ethnology or in its history (Argyrou, 2002). Inquiring into ethnology's scope in the twenty-first century allows us to reflect on the divergent disciplinary developments that make up the academic landscape of global anthropologies. Anthropology, like any other scholarly discipline, is not a universal endeavor but a historically contingent project infused with hegemonic power and national interests. It is also able to generate innovative energy and political critique.

Abstract

Ethnomethodology is a mode of inquiry devoted to studying the practical methods of common sense reasoning used by members of society in the conduct of everyday life. It was developed by Harold Garfinkel in an effort to address certain fundamental problems posed by Talcott Parsons' theory of action. Parsons' motivational approach to the problem of order (emphasizing internalized values) implicates an analytically prior cognitive problem of order involving the process by which concrete actions are produced and rendered intelligible in relation to their circumstances. Garfinkel's classic studies were designed to expose the methods of common sense reasoning that actors employ in this process. Contemporary research initiatives within ethnomethodology have revitalized a wide range of social science subfields, including the study of language and social interaction, the inner workings of bureaucratic and people-processing institutions, and the construction of formal scientific knowledge.

Ethnomethodology is a mode of inquiry devoted to the study of the practical methods of common sense reasoning used by members of society in the conduct of everyday life. The significance of this seemingly mundane subject matter resides in the fact that practical reasoning is what enables societal members to make sense of the circumstances in which they find themselves, find ways of acting in relation to those circumstances, and thereby contribute to the production and maintenance of an intelligible social world. Ethnomethodology, as the study of such reasoning practices, is thus concerned with the very foundations of social order.

It should be clear from this brief definition that ethnomethodology is not primarily a theory of social life, nor is it a methodology for the study thereof. It is in the first instance a discipline of inquiry devoted to a distinctive order of phenomena, one that is sometimes understood to be orthogonal to the concerns of mainstream social science. However, these phenomena have important theoretical, methodological, and substantive ramifications, and in the course of elucidating them ethnomethodology has had a major impact across a range of social science disciplines. Although it originated within sociology, ethnomethodology's sphere of influence extends to anthropology, cognitive science, communication, linguistics, psychology, and the philosophy of the social sciences.

Although a few studies appeared in the late 1950s and early 1960s, the nascent approach crystallized and attracted widespread attention in 1967 with the publication of Harold Garfinkel's *Studies in Ethnomethodology*. This was a time of great intellectual ferment in the social sciences, and ethnomethodology contributed in no small way to the revolutions that challenged prevailing theoretical perspectives and methodological approaches. In the domain of sociological theory, ethnomethodology helped end the dominance of the structural functionalist paradigm associated with Talcott Parsons, and led to a major reconceptualization of the theory of action and its relationship to social structure. It was also an important impetus behind the broad-based social constructionist movement that revolutionized theorizing about subjects ranging from deviance to gender. In methodology, ethnomethodological studies challenged the scientistic pretensions of positivistic research methods, and fostered greater sensitivity and self-reflection among methodologists of various stripes. Finally, ethnomethodology inspired numerous research initiatives that revitalized a wide range of social science subfields, including the study of language and social interaction, the inner workings of bureaucratic and people-processing institutions, and the construction of formal scientific knowledge.

Intellectual Origins

The origins of ethnomethodology can be traced back to seminal research conducted in the late 1940s by Harold Garfinkel in the course of his graduate work in sociology at Harvard University. Garfinkel was a student of Talcott Parsons and he took Parsons' voluntaristic theory of action as a basic frame of reference, but he was also deeply influenced by the phenomenological writings of Alfred Schütz and the teachings of Aaron Gurwitsch. (Sometime later, the ordinary language philosophy of Ludwig Wittgenstein would become another source of inspiration.) The phenomenological enterprise directed Garfinkel's attention to certain fundamental pretheoretical problems posed by Parsons' theory of action, problems which were not adequately addressed within the Parsonian framework. What would later come to be known as 'ethnomethodology' is in large part the result of Garfinkel's sustained effort to confront these problems by empirical means (*see* Parsons, Talcott (1902–79)).

Parsons had sought to develop a theory of social action that would solve the Hobbesian problem of order while retaining purposive human agency within its framework. At the same time, he wished to avoid the limitations and pitfalls of strictly utilitarian thinking, which cannot account for the ends toward which action is oriented, and which treats intrinsic rationality as the sole standard governing the selection of means. Parsons' solution centered around the role of moral values in social action – he proposed that, through socialization, such values become internalized and incorporated into the actor's personality, where they guide both the selection of ends of

action and the normative means by which they are sought. Insofar as such values are also institutionalized within a society and are shared by societal members, patterned activity and social cohesion will be the natural result.

Parsons' theory places primary emphasis on the motivational wellsprings of action, and in so doing it has relatively little to say about how concrete actions are managed and coordinated in real time. Thus, as Heritage (1987: 228) has observed, it is less a theory of action per se than a theory of the dispositions that give rise to action. Correspondingly, Parsons' theory fails to give serious consideration to the knowledge and forms of reasoning that actors themselves bring to bear in the course of producing and recognizing actual conduct. This insensitivity to actors' *endogenous* perspectives is exacerbated by Parsons' decision to define rational action in terms of an *exogenous* standard based on consistency with the application of scientific/logico-empirical methods. Any deviation from this standard is regarded as the embodiment of ignorance and error, in which case actors' own explanations of their actions may be dismissed in favor of a 'scientific' explanation cast in the language of norms and values.

Garfinkel recognized that Parsons' motivational solution to the Hobbesian problem of order implicates an analytically prior *cognitive* problem of order, one that cannot be resolved without due consideration to the common sense knowledge and practical reasoning employed by actors themselves. How do actors analyze their circumstances, determine which features are relevant for present purposes, and grasp what those features 'mean?' How do they know what forms of behavior will be recognized as normatively appropriate under those circumstances? How in other words is the fundamental intelligibility of action and circumstance accomplished? It is questions like these that Garfinkel sought to answer.

Garfinkel's Classic Studies

Although Garfinkel's central analytic questions were inspired by phenomenology, his way of addressing them was distinctively his own. He eschewed highly interpretive methods involving introspection or freewheeling *verstehen* in favor of a rigorously empirical approach based on close observation of social behavior. Since the methods of reasoning of interest are those embodied in social activities, they are publicly available to both lay members of society and professional analysts and are, at least in principle, eminently observable.

Analyzing such methods of reasoning-in-action, however, is intrinsically difficult because they are so deeply taken for granted. As an omnipresent resource for the management of social life, practical reasoning is not ordinarily an object of conscious reflection in its own right. Its very familiarity renders it elusive and resistant to analysis.

Garfinkel's ingenious solution to this problem entailed seeking out extraordinary situations in which the sense-making process is foregrounded, exaggerated, and hence rendered conspicuous. For the most part, these situations were engineered by Garfinkel and his associates through a series of experiments and quasi-experimental demonstrations. The situations often involved social actors encountering anomalous events – typically, particular social actions – that are incongruous with a pre-existing or default 'definition of the situation.' In one such experiment, subjects were engaged in a game of tic-tac-toe by experimenters who would erase and reposition the subjects' mark before placing their own mark on the grid. In another experiment, subjects were told to ask yes/no questions of a counselor but, unbeknownst to them, the 'answers' were given according to a random schedule. Elsewhere the focus shifted to incongruities that arise naturalistically rather than experimentally, and to the practices of social actors rather than observers – an example is the study of 'Agnes,' a person whose masculine genitalia and biography were at odds with her claim to female status. Across these examples, incongruity and its management served to throw processes of practical reasoning into sharp relief.

The results revealed that interactants would strive to render the situation as coherent and intelligible, invoking a wide range of background assumptions, contextual knowledge, and other elements of common sense – often in the form of natural language accounts – to this end. Three patterns of response were recurrent. Subjects would either (1) 'normalize' the anomalous event by reinterpreting it as consistent with the prior definition of the situation, (2) 'demonize' the event by treating it as a motivated and morally suspect departure from normality, or (3) reconstitute the environing situation so as to make it congruent with what is ostensibly taking place.

These outcomes demonstrate forcefully that interactants make sense of a given action by considering not only the intrinsic properties of the action itself, but also its relationship to the broader social environment in which it is embedded. The meaning and import of any particular action is thus thoroughly context-dependent. This would be a trivial matter if contexts were autonomous and stable – 'the' context of an action could then serve as an archimedian vantage point from which to disambiguate that action. Contexts, however, do not have such transcendent properties – the relevant context at any given moment is derived primarily from the actions through which it is composed, and even a single incongruous action can dramatically alter the context that is understood to be in play. Practical reasoning is thus a dynamic and reflexive process whereby the sense of particular actions and environing social situations are ongoingly adjusted and reconciled with one another. By implication, the experiential reality and temporal persistence of any social situation – whether a game of tic-tac-toe, a course of counseling advice, or a person's sexual status – rests upon a foundation of such reasoning practices.

Theoretical Implications

Garfinkel's findings amount to a major reconceptualization of the fundamental locus of social order. Most social science theories view social life as organized by structural entities (e.g., social institutions, cultural symbol systems, structures of race, class, and gender, etc.) that stand outside of the flow of events in everyday life and exert a more or less determining influence on the course of those events. Such theories embody what might be thought of as a *top-down* conception of social order. Garfinkel, in contrast, offers a thoroughly *bottom-up* conception, and this theoretical inversion is a natural consequence of his decision to treat social order as a cognitive rather than

a Hobbesian problem – not a problem of how conflict is avoided and solidarity maintained, but a problem of how the social world, whatever its character, becomes intelligible and accountable to its members. From this vantage point, every orderly feature of social life is an ongoing contingent accomplishment, the result of members' concerted effort to make those features recognizable to one another and the basis for subsequent action.

This theoretical inversion has further implications for the theory of action, and in particular for the role of social norms (as well as rules, conventions, etc.) in the conduct of action (Heritage, 1984, 1987; Wilson, 1971). In the traditional Parsonian view, norms regulate action by specifying what courses of action are appropriate under given circumstances. This view presupposes that situations, norms, and actions are independent entities, with each situation standing outside of the actions contained within it, and predefined norms constraining those actions to unfold along situationally appropriate lines. However, Garfinkel's findings about the nature of practical reasoning suggest that this viewpoint is fundamentally misguided. Far from being independent entities, situations, actions, and norms stand in a co-constitutive or reflexive relationship to one another. Correspondingly, actors are knowledgeable agents at the very center of this process, with the capacity to alter or transform the 'definition of the situation' through their actions, and to decide upon the sense and applicability of the norms deemed relevant to that situation. Thus, the experiential reality of social norms, like every other organized feature of social life, rests upon a foundation of practical reasoning whereby action is produced and rendered intelligible in normative terms. This does not mean that norms are inconsequential for social organization, but their primary significance is constitutive rather than regulative – norms play a crucial role as a resource for imputing meaning and motivation to situated behavior (*see* Action, Theories of Social; Norms).

Contemporary Research Initiatives

Following Garfinkel's classic studies, ethnomethodological research developed in a number of fruitful directions. While some researchers continued to elucidate the generic properties of practical reasoning (e.g., Pollner, 1987), most shifted toward examining such reasoning as it is applied in various specialized domains of social life. At the same time, the predominant research methods employed by ethnomethodologists underwent a corresponding shift away from quasi-experimental designs and toward more naturalistic methods involving the direct observation of ordinary conduct. The resulting corpus of studies resists easy summary, but three prominent lines of work will be distinguished.

People-Processing Institutions

Ethnomethodologists first explored various organizational environments involved in people processing: schools, public welfare offices, police departments, and so on (e.g., Cicourel, 1968; Sudnow, 1965; Wieder, 1974). These studies repeatedly documented the inadequacy of codified rules, formal procedures, and informal norms as explanations of organizational conduct. Rules and allied phenomena fail to capture the elaborate judgmental work necessary to implement the rules in concrete circumstances, and more generally to perform competently the tasks intrinsic to each setting. These previously unexamined professional competencies and discretionary judgements became the focus of close scrutiny and sustained analysis, shedding new light on the complex inner workings of people-processing institutions.

The findings have important implications for our understanding of organizational decision-making and its products. The institutions under examination routinely generate official designations of persons (e.g., 'criminal,' 'juvenile delinquent,' 'qualified welfare recipient,' etc.) and their actions (e.g., 'burglary,' 'assault,' etc.). Such designations do not result from workers mechanically applying clearly defined criteria to each case, but involve various ad hoc considerations guided by common sense knowledge of what outcome would be normal and reasonable under the circumstances. Insofar as the resulting designations form the basis for calculations of official statistics (on rates of crime, mortality, poverty, etc.), these studies also cast doubt on the validity of official statistics and their value for social scientific research (*see* Bureaucracy, Sociology of).

Science and Technology

Ethnomethodologists have also ventured into the laboratory to explore the highly technical competencies that underlie the creation of scientific and mathematical knowledge, and the production and use of technological artifacts. This line of research is most closely associated with the later work of Garfinkel himself and his immediate associates (e.g., Livingston, 1986; Lynch, 1993). It is reminiscent of Edmund Husserl's later writings on the European sciences in that a primary objective is to elucidate the unexplicated foundations of scientific knowledge. However, where Husserl's enterprise was essentially philosophical in character and retained a phenomenological concern with transcendental consciousness, the ethnomethodological approach proceeds empirically by examining publicly available details of situated 'workbench' practices.

Much research in this vein is concerned with the genesis and reproduction of technical discoveries ranging from physical objects to mathematical theorems. Such discoveries are arrived at, accountably validated, and made intersubjectively available through complex courses of practical reasoning and embodied activity that receive scant attention in scientific texts. This may seem surprising, given that scientists are supposed to document their own methods so as to permit replication, but scientists' methodological descriptions – like all abstracted accounts of situated action – are necessarily incomplete. Ethnomethodologists thus seek to recover the mundane praxiological foundations of discovering work, and in so doing they re-specify discovered objects as locally produced and naturally accountable achievements. Furthermore, the very concept of discovery is transformed by this research. If physical and mathematical objects are unavoidably intertwined with situated practices, then the discovery of any such object is at the same time the discovery of a substrate of practices through which that object

may be accountably produced and reproduced within concrete situations.

Ethnomethodological studies of science and technology hold the promise of yielding findings that represent recognized contributions to the various technical disciplines being studied. Indeed, the practical value of ethnomethodology is increasingly recognized in computer science, software engineering, and human–computer interaction (Suchman, 1987; Button, 1993).

Talk and Social Interaction

Perhaps the most widespread contemporary variant of ethnomethodology is what has come to be known as *conversation analysis*. This burgeoning field was developed by Harvey Sacks, originally Garfinkel's student and colleague, in collaboration with Emanuel Schegloff and Gail Jefferson (e.g., Sacks, 1992; Atkinson and Heritage, 1984).

Conversation analysis (henceforth CA) involves the study of practical reasoning as it is put to use in the conduct of spoken interaction. The domain of interaction – what Erving Goffman referred to as *the interaction order* – is more general than any of the specialized institutional domains investigated by ethnomethodologists, for interaction lies at the heart of virtually all of these institutions and extends as well to informal encounters between persons. Moreover, in the history of the human species, interaction developed long before other societal institutions came into being, and is in this respect 'the primordial site of sociality' (Schegloff, 1988).

CA differs from other lines of ethnomethodological research not only in substance but in methodology. Conversation analysts rely exclusively on audio- and video-recordings of interactional data, and transcripts that capture the details of interaction as it actually occurs. Such data have numerous advantages – they can be examined repeatedly, analyzed at an unprecedented level of detail, and reproduced in published works so that readers can independently assess the validity of analytic claims.

The resulting research enterprise has generated an impressive array of interlocking and cumulative findings on a wide range of subjects. These include the organization of turn taking, action sequences, lexical choice, the relationship between talk and nonvocal activities, and the collaborative management of various interactional activities (e.g., giving advice, delivering good and bad news, telling troubles, etc.). More recently, researchers have applied the analytic resources of CA to various phenomena that intersect with, and can be informed by, the study of talk-in-interaction. These include how talk is organized in various institutional settings, and how it serves as a medium for the accomplishment of occupational tasks such as medical examinations, classroom lessons, journalistic interviews, trial examinations, and so on (e.g., Boden and Zimemrman, 1991; Drew and Heritage, 1992). Researchers have also begun to explore how the study of talk-in-interaction can illuminate linguistic phenomena such as grammar (Ochs et al., 1996), as well as medical disorders such as aphasia that manifest themselves at the level of speech (Goodwin, 1995; Heeschen and Schegloff, 1999).

This article is a complete revision of the previous edition article by W.P. Lehmann, volume 7, pp. 4874–4877, © 2001, Elsevier Ltd.

Abstract

This article begins by defining etymology as both the identification of word origins and the preparation of histories of individual words or word families. It next offers a brief overview of the history of this linguistic subdiscipline. The article then discusses such topics as the relationship of etymology to other branches of historical linguistics, the diffusion of the findings of etymological research (especially in etymological dictionaries), theoretical and methodological questions, and the insights provided by etymological reconstruction of the lexicon of undocumented language states into the cultures and social structures of past historical periods.

Definition and Scope of Etymology

Etymology can be concisely defined as the search for and identification of the origin of a given word in a specific language or of a given series of historically related words in a language family. It is the etymologist's responsibility to uncover and describe the morphophonological form and the semantic range of the base that forms the starting point for the evolution over time and space of the lexical item under investigation. For many specialists in this field, etymology has come to designate the preparation of the complete history or biography of a word. Identification of the word's immediate formal and semantic origin is now but the first step in this task, which includes accounting for all facets of the chosen word's formal and semantic history, the derivatives to which it has given rise, its rivalry with other referentially similar lexical items, its spread into other languages as a loanword (if appropriate) and, when relevant, the circumstances leading to its demise or slide into obsolescence. This approach to etymology seems feasible only for languages with a long and abundant recorded history. Etymology is consequently an integral part of the broader discipline of diachronic lexicology.

In general terms, a given word can (1) form part of the language's inherited lexicon, (2) represent a borrowing from a language with which the language under study has come into contact, or (3) result from the various (often language-specific) internal processes of lexical creation available to speakers, such as prefixal and suffixal derivation, infixation, compounding, sound symbolism, and lexical blends. The identification of the elements that fall into each of these three broad categories in a specific language forms part of the brief of etymology, the sole linguistic discipline that is exclusively diachronic in scope. Most etymological research devoted to individual languages or language families concentrates on the history of the inherited lexicon, and, to a lesser extent, on loanwords. Derivatives have traditionally received far less attention. Yet, the history of each apparent derivative deserves individual study in order to differentiate authentic derivatives created within the language at issue from those which, genetically, are actually inherited from the lexicon of the ancestor language, or are borrowings from yet another language (e.g., the many Spanish derivatives in – *aje* which, for the most part, are borrowings from neighboring Gallo-Romance and Catalan). Etymology is one branch of historical linguistics that needs to make use of the findings of many of the other fields, such as phonology, inflectional and derivational morphology, syntax, semantics, and lexical typology, as well as relevant extralinguistic knowledge garnered from the study of political, social, cultural, and literary history, and textual criticism. Unless the analyst is dealing with the lexicon of an isolate language (such as Basque), research into the history of the lexicon of an individual language needs to be comparative in nature, with the presentation of cognates from other members of the relevant language family. Often, evidence from a related language may tip the scales in favor of one of several competing etymological hypotheses, or even point the way to a new solution. Even when dealing with an isolate language, comparative evidence from attested regional varieties of that language may be useful in etymological reconstruction.

Etymology in the Past

The origin of words has attracted the attention of scholars and thinkers interested in human language for over two millennia. Early philosophers thought that the original meaning of a word reflected its true essence, a belief reflected in the Greek label *etymologia* (a compound of *etymos* 'true' and *logos* 'word'). Such etymologizing plays a significant role in various religious traditions. The Bible and the subsequent Jewish and Christian traditions of biblical exegesis contain numerous passages in which the text seeks to identify the original essential meaning of a word, especially of personal and place names. A similar approach to the relationship between linguistic signs and the realities that they name is found in the Chinese *Shih ming* (*c*.CE 200). Old French *ethimologie* and Old Italian *etimologia* are documented in thirteenth-century texts. English *etymology*, rarely found before the sixteenth century, is a borrowing from Old French. With the awakening of scholarly interest in vernacular languages during the Renaissance, there began to appear in the sixteenth and seventeenth centuries, etymological dictionaries of numerous European languages. Many of the etymologies proposed in these prescientific works are fanciful, often based on fortuitous formal and semantic resemblances.

In the western scholarly tradition, etymology became a truly scholarly discipline only with the establishment of the comparative method and the founding of Indo-European (IE) comparative linguistics in the early nineteenth century with its emphasis on the regularity of sound change, a basic underlying principle of etymological research and reconstruction. This period witnessed the publication of the first great etymological dictionaries of IE languages (e.g., Pott, 1833–36; Diez, 1853; Fick, 1871; Kluge, 1883). As a scholarly discipline, etymology forms part of the European linguistic tradition. The major etymological dictionaries of numerous non-European languages and language families were prepared over the course of the last century by European and American experts.

Etymology and Other Linguistic Fields

Etymology finds itself in a symbiotic relationship with some of the other disciplines of historical linguistics. In 1875, the American pioneer William Dwight Whitney (1827–94) declared (echoing thoughts voiced earlier in the century by Jakob Grimm): "The whole process of linguistic research begins in and depends upon etymology" (quoted in Malkiel, 1993: 20). The sound correspondences that form the backbone of the study of a language's formal evolution are extrapolated from a large quantity of accepted and verified etymologies. An equally reliable etymological database is needed to study the patterns of semantic evolution. Yet, a deep knowledge of formal and semantic evolutionary patterns identified on the basis of well-established etymologies is essential for the reconstruction or identification of the etymon of the many words in a language whose origins are unclear, controversial, or completely unknown. Many of the nineteenth-century pioneers of etymological research authored both historical grammars and, separately, etymological dictionaries of the same language or language family, for example, Jakob Grimm (1822–1837, 1854–1960 (the latter work was carried out in collaboration with his brother Wilhelm Grimm)) for German and Friedrich Diez (1836–1844, 1853) and Wilhelm Meyer-Lübke (1890–1902, 1911–1920) for Romance. In all three cases, publication of the historical grammar preceded the corresponding etymological dictionary. The close relationship between etymology and other fields of historical linguistic research constitutes one of the main themes running through the etymological writings of the Romanist Yakov Malkiel (see, for example, the essays collected in Malkiel, 1968).

Etymology has to distinguish between the immediate and the distant origin of the word under study. Etymological studies of the lexicon of a specific language tend to work backward from the modern language. Historians of each language or language family must delimit, in light of the available linguistic and extralinguistic data, how far back in time to trace the word's origin. For example, etymological studies of the inherited lexicon of a Romance language traditionally seek to identify the appropriate (documented) Latin base of a Romance word, without discussing the more distant Italic or IE origin of the relevant Latin form (although there are exceptions, such as the Indo-Europeanist Giacomo Devoto's *Avviamento alla etimologia italiana*, which identifies, when relevant, the IE root of the etymon). In the case of the numerous borrowings from other languages that entered each Romance language through contact situations, the etymologist will identify the etymon that entered from the immediate source language, without elaborating on its origins in the donor language. To give but one example, the historian of the Spanish lexicon will identify Spanish *azul* 'blue' as a borrowing from Arabic (its immediate origin) but will not discuss the circumstances of this word's entry into Arabic from Persian. On the other hand, the author of an etymological dictionary of Gothic can choose to identify either the proto-Germanic or the proto-Indo-European root of the lexical item under examination.

Etymology and Reconstruction

On the basis of cognate sets, the oldest available data, and the application of the comparative method, etymological dictionaries for most languages or language families strive to reconstruct undocumented roots as the appropriate starting points. Practitioners of Romance etymology are blessed (or cursed?) by having at their disposal the rich documentation afforded by written Latin, reflecting the different written registers of the spoken language (labeled variously as Spoken Latin, Vulgar Latin, and Proto-Romance) underlying the Romance languages. Traditional Romance etymology has contented itself with presenting as the etymon the form of the base as it appears in written Latin, with asterisked hypothetical bases invoked as a last resort in the absence of a written Latin correlate. Often, the standardized orthography of the traditional Latin form masks the phonetic reality of the etymon in the spoken language, which can be recovered through application to the Romance data of the comparative method. This is the underlying principle of the *Dictionnaire Étymologique Roman* project codirected by Eva Buchi and Wolfgang Schweickard, in which the Proto-Romance starting point is presented in phonemic transcription (although the Romance descendants are offered in standard orthography). Each entry ends with explicit reference to the relevant form of the base in written Latin. I shall offer one example of this procedure. The Romance data permit the reconstruction at the level of Proto-Romance of the bases */askUlt-a-*/eskult-a-/, which correspond to ausculty */eskult-a-/are 'to listen' of written Latin. This use of comparative reconstruction in Romance etymology has been the subject of a lively debate among specialists (see, for example, Varvaro, 2011a,b and, in response Buchi and Schweickard, 2011a,b).

The attempt to identify the etymologies for a language whose genetic affiliation is uncertain poses different problems. Well-established cognate sets play an important role in the reconstruction of etymological bases. In the case of very large language families such as Sino-Tibetan Burman or Austronesian, whose genetic subgroupings are highly controversial, the etymologist must take care in weighing the role of possible cognates in an etymological reconstruction, and must distinguish between formal and semantic resemblances that reflect actual genetic affiliation versus those that may result from processes of language contact.

Over the years etymologists have refined their techniques for reconstructing the form of the relevant bases underlying the words or word families under study. The semantic side of

the (reconstructed) base has not been a primary focus of etymological research. Emile Benveniste's seminal study (1954) lays out many of the difficult and complex issues involved in semantic reconstruction. Typical is the declaration made in Orel (2003: xii): "The semantic reconstruction of the proto-Germanic words was not even attempted: too many complications and arguments would have followed the decision to ascribe meanings to Proto-Germanic words." Only recently have some specialists attempted to apply the principles of the comparative method to the reconstruction of the semantic range of the proposed etymological base. It would be reasonable to assume that meanings shared by all or many of the descendants of a given base (reconstructed or documented) go back to the semantic range of that item in the protolanguage. Meanings found only in a small number of geographically scattered cognate forms may reflect inheritances from the protolanguage, or, alternatively, might result from independent but parallel semantic innovations brought about by the working of such cognitive processes as metaphor and metonymy. It is certainly realistic to posit polysemy at the level of the etymon (Rankin, 2003). One of the innovative features of the aforecited *Dictionnaire Étymologique Roman* is its meticulous reconstruction and systematic ordering in each entry of the semantics of the posited proto-Romance base. The reconstructions are based on the attested semantic range of each Romance cognate rather than on the meanings of the written Latin equivalents.

Etymological Dictionaries

Etymological dictionaries of entire language families can adapt a prospective perspective, taking as the starting point for each entry the documented or, more often, reconstructed lexicon of the source language, and tracing the evolution of each base into the individual descendant languages. This approach is also feasible for the study of the vocabulary of individual languages. In addition to the pan-Romance *Romanisches Etymologisches Wörterbuch* (1911, 1920_3), the multivolumed *Französisches Etymologishes Wörterbuch* (von Wartburg et al., 1922–2002) and the ongoing *Lessico Etimologico Italiano* (Pfister, 1979) are arranged alphabetically by etymon. A similar structure is found in the innovative and methodologically controversial *Dictionnaire Étymologique Roman*, whose entries are arranged according to the reconstructed proto-Romance base (presented in phonemic transcription), rather than by the written Latin equivalent. This dictionary has limited its scope in its first stage of elaboration to approximately 500 proto-Romance bases that have survived into all, or most of, the Romance languages. However, this prospectively arranged system poses serious problems when deciding in which entry to place the many lexical items in the target language whose origins are far from transparent. The team responsible for the continuation of the *Französisches Etymologishes Wörterbuch* has had to prepare several fascicules, arranged by semantic categories, devoted to words of unknown origin. In dictionaries arranged according to the etymon, indexes of the words studied are essential for the nonspecialist reader interested in the origin of a specific word.

Etymological information can be transmitted in several forms. The layperson seeking to know the origin of a given word in a specific language will often find a concise identification of the etymology in the relevant entry in a monolingual reference dictionary. For example, most dictionaries of, say, French will tell the reader of the entry for *père* 'father' that the word comes from the Latin *pater*, but will not explain the formal or semantic details of its evolution. With regard to the origin and history of words whose etymology is unknown or disputed, specialists usually pass on their findings or hypotheses to their colleagues in the form of brief notes or more elaborated articles in scholarly journals, usually read only by specialists. Far less frequent today are monographs or even books devoted to the detailed study of the history of individual words or of entire word families. The culmination of etymological research on the lexicon of a language or language family is the etymological dictionary where each entry discusses, insofar as is feasible, the given word's formal and semantic history, as well as offering, when appropriate, a scholarly justification for the proposed etymology and, if appropriate, a critical review of competing explanatory hypotheses. Indeed, it is often an etymological dictionary whose entries make available to the wider scholarly community the findings first reported in detailed and specialized etymological articles and monographs.

Today, most major languages or language families have at least one etymological dictionary devoted to their lexicon. An excellent and thorough critical overview (with bibliography of primary and secondary sources) of such dictionaries appears in Eva Buchi's contribution to the forthcoming *Oxford Handbook of Lexicography*. Malkiel's (1976) typology of etymological dictionaries retains its value. He adduced eight criteria for classifying such dictionaries: (1) time depth (period to which the etymologies are traced back), (2) direction of analysis (prospection or retrospection), (3) range (languages dealt with), (4) grand strategy (structural division of the dictionary), (5) entry structuring (linear presentation of the chosen features), (6) breadth (information given in the front- and back matter vs within the individual entries), (7) scope (general lexicon vs parts of it, e.g., borrowings), and (8) character (author's purpose and level of tone).The entries in most such dictionaries are arranged alphabetically by the word whose origin it seeks to elucidate or by the chosen etymon, rather than by semantic categories or lexical families.

Etymology, Theory, and Methodology

For the most part, etymologists prefer to devote their efforts to the identification of etyma and the preparation of word histories/lexical biographies rather than to discussions of methodology and theory. Although Jules Gilliéron originally coined his famous dictum 'Each word has its own history' as a response to the Neogrammarian view of the rigidity of the so-called sound laws, his words could equally apply to lexical history, including etymology. Each etymological solution is unique. Consequently, etymology is a linguistic subdiscipline that does not readily lend itself to rigid methodological systematization or vociferous and polemical theoretical debate. There can be no unified theory of etymological analysis, a situation that may account for the current estrangement between etymology and general historical linguistics. Some renowned etymologists (e.g., Vittorio

Bertoldi have gone so far as to describe etymology as an 'art' (cf the title of his introductory manual L'arte della etimologia (1952)).

Etymology no longer occupies a central place in the discourse of historical linguistics. Etymological method today seldom receives lengthy attention in manuals and handbooks of historical linguistics and is rarely afforded separate book-length treatment. Notable recent exceptions in the English-speaking world are the overviews of etymology by Anatoly Lieberman (2005) and Philip Durkin (2009) aimed at the educated nonspecialist reader. At the beginning of the twentieth century, Romance etymologists debated the relative weight to be accorded to formal versus semantic criteria in resolving complicated etymological cruxes. In retrospect, this was a pointless discussion, as the etymologist must weigh all the relevant linguistic (and, if appropriate, nonlinguistic) evidence. There exists no algorithm for evaluating each case. Etymology is language specific, and most etymologists specialize in the history of one language or one language family. It is next to impossible to identify etymological universals. Can we even speak of 'general etymology' in the same way as 'general phonetics' or 'general semantics?' A comparative etymological analysis of the lexicon of individual languages or language families undertaken by a team of specialists may identify certain semantic fields or grammatical categories that possibly contain a high number of elements of unclear origin, or may reveal certain cross-linguistic patterns in lexical history. In the Romance languages, the origin of many of the words corresponding to 'boy, child' is controversial: Fr. *garçon*, Sp. *muchacho*, *niño*, *chico*, *mozo*, Ptg. *rapaz*, It. *ragazzo*, and Rum. *băiat*. Although outside the Romance domain, one may include here the English *boy*, originally 'servant.'

Etymology, Loanwords, and History

All words evolve in a historical, cultural, and social context. For many etymologists (including the author of this article), the opportunity to study lexical history in such a framework is one of the joys of humanistically slanted diachronic lexical research. The link between diachronic lexical studies and material reality can be seen in the *Wörter und Sachen* school of dialect geography that flourished among European linguists in the first half of the twentieth century. Such studies focused, from a historical perspective, on how a language or group of languages expressed a given reality of material civilization (e.g., animal-, plant-, bird-names, farm implements, tools, etc.). The identification and analysis of loanwords resulting from language contact (at the level of both oral and written language) require close examination of the relevant extralinguistic circumstances, including accurate dating and philological analysis of the first documentation of the relevant forms in both the source and recipient language. A loanword can exist in the recipient language for a long time before it surfaces in a text, the only source of documentation for past stages of the language. The historical study of loanwords requires the etymologist to study the integration and diffusion of the neologism through the speech community, processes that may take a long time after its introduction into the host language (for an example of the application of this approach to Spanish, see Dworkin, 2012). A recent cross-linguistic study of loanwords in about 40 languages (Haspelmath and Uri Tadmor, 2009) has demonstrated that lexical items belonging to certain semantic fields (e.g., emotions and values, motion, kinship, spatial relations, body parts, and sense perception), semantic areas that are universal to all human societies, are rarely borrowed. In contrast, fields such as clothing and grooming, religion and belief, the house, law, agriculture and vegetation, social and political relations, food and drink, domains subject to a high degree of intercultural influence, show higher rates of borrowing. These considerations may guide etymologists in deciding in doubtful cases whether it is reasonable to propose that a specific word may be a borrowing. The results of etymological research form the foundation of a subfield known as linguistic paleontology, whose findings allow historians to analyze (more often than not, reconstructed) lexical data in order to recover details or formulate hypotheses concerning early (often prehistoric) societies, their religious beliefs, their kinship systems, the structure of the local economy, etc. (cf the attempts to reconstruct diverse facets of proto-Indo-European society, or the attempts to use specific items of the reconstructed lexicon to locate the homeland of speakers of proto-Indo-European).

Abstract

Eudaimonia and concepts of the good life and human flourishing have been of central concern for philosophy and not least with reference to Aristotelian thought. Tied to the Self, the relations to others and the just political order, it has been one of the key concepts of ethical-political thinking during the seventeenth and eighteenth centuries and – despite the eviction of *eudaimonia* in Kantian reasoning and the categorical imperative – has been revived in various strands of utilitarianism, critical thought, moral philosophy, virtue ethics, and (feminist) ethics of care.

Eudaimonia (lit. 'a good demon,' *Glück*, *prospérité*, *bonheur*, happiness, human flourishing, good life) has been one of the central concepts of ethics and philosophy. Happiness or better: the good life was, for once, connected to virtue; it was conceptualized in subjective terms, with reference to the self, to the (restraining of) passions and affects, to self-realization and the realization of personal objectives, or of one's overall life. Second, happiness has been cast in relation to the other, as friendship, love, recognition, as ethically founded intersubjectivity. Third, it has been connected to the just political order. The notion can be traced from its 'classical' conceptions in Aristotle, the Epicurean and stoic traditions, to its reelaboration in the philosophy in early modernity to Kant, who radically evicted the connection of happiness with virtue. Despite Kant's subjectivation of happiness, the notion returned persistently into the political realm – as 'redemption,' 'the principle of hope,' as 'emancipation,' 'undamaged life' (Frankfurt School), and, in the version of existentialist philosophy, as 'authenticity,' up to recent attempts of philosophy to found happiness in a just order, as, for example, in John Rawls, Martha Nussbaum, and Martin Seel, in virtue ethics and moral philosophy (Elisabeth Anscombe, Bernard Williams, Alasdair MacIntyre) or (feminist) ethics of care (Carol Gilligan, Virginia Held, Nel Noddings).

Following up on the ancient concepts of *eudaimonia*, the notion has been given a great variety of different meanings. Its semantic range reaches from 'the favor of fate, the advantageous lot, the happy circumstance,' all referring to accidental, external circumstances, to action and achieved goals making up the 'good life.' Across this breadth, thus, the term includes that which is outside of the reach of human beings, i.e., destiny (as in the ancient figures of *Tyche* or *Fortuna*, the goddess of fate, who blindly distributes her offerings), as well as a durable state that can be influenced and, in principle, achieved by virtuous human action. Precisely, the determination of such action, guided by the pursuit of happiness, has long been the basis of ethics and moral philosophy and of their debates about action guided by virtue, which then in turn was to determine and safeguard happiness and the good life (Caillé et al., 2001).

Eudaimonia is thus one of the central concepts of ethics and moral philosophy. It has been cast in a variety of ways and points into a number of different directions. Happiness was, for once, conceptualized in subjective terms, with reference to the self (*see* Self: Philosophical Aspects), to the passions and affects, to the realization of one's objectives, or of one's overall life. Second, it can be cast in relation to the other, as friendship, love, recognition, care, as ethically founded intersubjectivity. And finally, happiness and the good life have been connected to the community and its just political order. Even though this relation found its strongest expression in ancient philosophy, it has by far not disappeared from current discourse. In contrast, it may possibly even be claimed that the emphasis on justice as a precondition for happiness and the 'good life' presents, just as much as the reference to the self and to the other, an inescapable point of concern of modern (moral) philosophy. Additionally, conceptualizations of happiness show a temporal tension between fulfillment across all of the life span, on the one hand, and fulfillment in the sudden and epiphanic moment, on the other. Further, it is marked by a transcendental religious tension that stretches from revelation, redemption, and salvation to joy. It carries with it a political–social–ethical tension between an individualistic view of personal self-realization and the conception of a good and just political order. Finally, a tension with regard to a theory of action is unavoidable, a tension that situates the singular human being between the capability to act autonomously and fate, destiny, and luck (Nussbaum, 2001). In a variety of ways, these tensions can be traced back to the heritage of Greek reason.

The 'Classical' Tradition

In the Nicomachean Ethics (Nagel, 1980; Destrée, 2003), engaging with Plato's conception, Aristotle links the concept of *eudaimonia* to the three human life forms (Wolf, 1996): to pleasure, from which most human beings gain their view about what happiness is; to the service of the state; and to life dedicated to philosophy. Because reason is a distinctively human capacity, neither profane enjoyment nor politics and the art of governing, but *theorein* is the highest in the hierarchy of human activities, in which *eudaimonia* can be realized. "Happiness is activity (*energeia*) in accordance with virtue" (X, 7) and "the highest good reachable for human beings presents itself as the activity of the soul in the sense of its essential prowess (*areté*)" (Aristotle, 1934: I, 6, see Heidegger, 1992). The activity of *theorein* is aiming at the cognition of that which is eternal. Being independent of changes in the external circumstances it is the most persistent among human activities. Is full of pleasure – on the one hand, because it is continuous and stretches across an entire life; on the other, because it participates in the eternal

 http://dx.doi.org/10.1016/B978-0-08-097086-8.26027-3

that it gets to recognize. Furthermore, to be active in the sense of *theorein* is a purpose for itself, the final telos, that which is pursued for its own sake, since it does not produce anything that lies outside of itself; it is self-sufficient. For Aristotle, happiness is an eminently social and political matter. It is tied to the polis, a just political community and is as well not accomplished without friendship, without the relations to others. Aristotle, thus, linked happiness to human essence in need to be actualized, to the relation to others in friendship, and to institutionally supported forms of living and acting together (Garver, 2011). With the disruption of the order of the polis as well as of Hellenic philosophy, in contrast, for the Stoa and for Epicurean hedonism (and as well for skepticism), *eudaimonia* becomes a concept that refers to purposes that reside in that which is available to human beings. *Eudaimonia* is, then, the striving for whatever is available and, vice versa, it asks for the diminution of demands and the avoidance of pain. Despite all differences between these ancient Greek schools of thought, they also show commonalities, such as in particular in the connection of virtue and happiness. Ancient Greek philosophies, as Kant stated, follow the same method in rejecting any validity to the assertion that virtue and happiness could be two separate elements of the highest good. They "consequently sought the unity of the principle in accordance with the rule of identity," even if they differ in the choice of the fundamental concept. "The Epicurean said: to be conscious of one's maxim leading to happiness is virtue; the Stoic said: to be conscious of one's virtue is happiness. For the first *prudence* was equivalent to morality; for the second, who chose a higher designation for virtue, *morality* alone was true wisdom" (Kant, 1993a: A 200, pp. 239–240/book II, chapter 2, p. 229).

Eudaimonia in the Philosophy of Early Modernity

Conceptions of happiness relating individuals to society changed profoundly during the period known as early modernity; these changes were part of broader reproblematizations in the moral and social philosophy of the time. Political thinking of this period introduces happiness as a component and as a means of politics. Happiness becomes one of the key concepts of ethical-political thinking during the seventeenth and eighteenth centuries, a thinking that at the same time reorders the relations between the concepts for affects and those for morality. No longer the affective drives of the human beings are the object under consideration, but rather human actions and their consequences. Affects as such are considered neither as good nor evil, it is rather individual selfishness and self-love (*amour-propre*) that moves into the center of concern (Mauzi, 1969). This focus generates the new problématique of moral philosophy: If it is the case that human beings pursue their happiness on the basis of their drives and affects, then it is the task of moral philosophy to determine how – despite that – a good social order can exist and be maintained.

The new emphasis on the consequences of individual action went along with a reconceptualization of the political. From now on, it was precisely their striving for happiness that made human beings inclined to subject themselves to the common order. This reasoning emerges in classical form in Thomas Hobbes's (1588–1679) *Leviathan*. Hobbes first determines 'felicity' as the attempt to completely accomplish the objectives of human desires. Since, however, all human beings hope to reach this goal, the one potentially turns into a danger for the other. To avoid such a situation of *bellum omnium contra omnes*, of 'war of every man against every man,' human beings assemble to form a state that itself embodies no longer any conception of happiness or of the good life, but that guards to prevent any situation from arising in which the various strivings for happiness collide.

At the end of this period, during which happiness remains the focal point of theoretical constellations, an attempt is made to indeed erect a polity that is committed to support its members' striving for happiness. The American Declaration of Independence even declares the 'pursuit of happiness' to be a human right (Jefferson, 1776). A historically novel compromise is here elaborated between a classic substantive and an individualistic instrumental conception of the state: the state respects the autonomy of the individual and the plurality of their views, but does not entirely renounce the proposition of a general guiding idea about the 'good life.' The individuals' striving for happiness – to the protection of which the state has been created, exactly in the sense of the theories of delegation – in its sum produces the common good. This common good, however, is now in a particular way mixed with elements of a Protestant ethic, in which inner-worldly happiness, for example, as economic success, gains divine approval. This unique privileging of the pursuit of happiness as a human right, which cannot be found in European declarations, is rooted in a particular relation between the state and the citizens. It is nevertheless close to European conceptions in another respect, namely in understanding the citizen predominantly as an economic subject, a *bourgeois* in contrast to a *citoyen*, whose pursuit of property needs to be protected by the state, a protection that is considered as being the primary task of the state.

The utilitarianism of the eighteenth and nineteenth centuries similarly still places happiness in the center of moral and social philosophy (*see* Utilitarian Social Thought, History of). The ethics of utilitarianism considers individual – as well as general – utility as the purpose of action and sets thus 'good' synonymous with 'useful.' Jeremy Bentham (1748–1832) calls for 'the greatest happiness of the greatest number' as the collective goal; by promoting the well-being of all, the well-being of the individual is promoted as well. Morals and legislation are that art to regulate human actions such that to bring forth 'the greatest possible quantity of happiness' (*An Introduction to the Principles of Morals and Legislation* 1789). Drawing on Bentham, John Stuart Mill (1806–73) considers the pursuit of the greatest possible happiness of all as the supreme goal as well (*Utilitarianism* 1861). On the one hand, utilitarianism maintained a conception according to which the pursuit of happiness is the most important motive of human action, and it also kept the link between happiness and politics. What was added were amendments that had become historically unavoidable, namely the view that every human being determines their happiness in their own way and strives for it, and that everybody has the same right to do so. On the other hand, however, an *aporia* between the common good and the diversity of the human pursuits of happiness had been created. This *aporia* was to be dealt with by assuming the comparability of the various individualized and

subjectivized pursuits. Measurability and quantification were the tools to make the diverse compatible, since the state's task to pursue the greatest happiness of the greatest number demanded the possibility of adding up the manifoldness of forms of individual happiness. Quantification of happiness is the attempt to maintain a measure for collective happiness by at the same time making only a minimum of substantive assumptions about happiness as such. Utilitarianism had inevitably to fail when radically subjectivized conceptions of happiness were to be compared to each other, measured and sublated in an overall concept of utility.

The Eviction of Eudaimonia from Philosophy: Immanuel Kant

In continental moral and political philosophy, the most systematic attempt to reorder the relation between action and happiness was undertaken by Immanuel Kant – it was at the same time an attempt with far-reaching consequences for later philosophy. Moral philosophy had tried to demonstrate that there is no, and could not possibly be any, contradiction between ethical demands on the one side, and the pursuit of happiness (or of utility or interest) on the other. Thus, it stated that virtuous action promotes happiness. Kant radically breaks this connection of virtue and happiness.

Happiness remains for Kant as well a concept that has a basic influence on human action: "Happiness is 'the satisfaction of all our desires'; *extensive*, in regard to their multiplicity; *intensive*, in regard to their degree; and *protensive*, in regard to their duration" (1974a: II, B 834, p. 677 [p. 518]), "*happiness* is the state of a rational being in the world in the whole of whose existence *everything goes according to his wish and will*, and rests, therefore, on the harmony of nature with his whole end as well as with the essential determining ground of his will" (1993a: A 224–225). This concept, however, is not suitable as a foundation of moral philosophy, according to the following reasoning.

First, happiness can hardly be the true purpose of nature, since in such a case, human action would not be guided by practical reason, steering the will, but subjected to the instincts (1993b: BA 5, p. 20). Second, the concept of happiness cannot be determined unequivocally, since it rests on experience, which is never closed, on the one hand (1993b: BA 46, p. 47, 1993a: A 46, p. 133), and since, on the other hand, the 'idea of happiness' requires an absolute whole, a present and future maximum of well-being. The contradiction between the principled openness of experience and the idea of the accomplishment of happiness cannot be sublated within time. Furthermore, the conception of a reachable maximum of happiness is impossible for two reasons. No sum of happiness can ever be added up, since only similar perceptions can be added up; feeling, however, is highly variable according to the manifoldness of being touched in the very intricate state of life. In addition, the nature of the human being can never halt and be satisfied in possession and enjoyment. The inclinations change, they grow, and they always leave an even larger emptiness behind them than the one hoped to fill. (The dynamics of needs and their limitless character (*apeiron*) was already of concern for Hellenic philosophy.) The fact that each human being may have a specific view of happiness, and which furthermore may undergo change in the course of life, puts a further limit to any general determination of happiness. Happiness is "a subjective basic feeling of enjoyment of dissatisfaction" (1993a: A 46, p. 133); a subjective feeling, however, cannot be the foundation of general rules for action. As a consequence, thus, it is not possible to demand the agreement of the pursuit of happiness with moral requirements – which precisely was the former assumption: that namely the pursuit of happiness realizes ethical requirements since happiness resides only in virtuous action.

Such subjectivization separates happiness from virtue and ethics and subordinates it to the categorical imperative. "Act in such a way that the maxim of your will could always serve as the principle of a general law." It is no longer the pursuit of happiness that makes an action moral, but only the respect of the moral law and the obedience to duty, since it is only in them that human freedom is anchored. The categorical imperative relates to "the idea of freedom" (1993b: BA 102–103, p. 84), since free will is nothing but "autonomy, that is, the property of the will to be its own law" (1993b: BA 97–98, p. 81). Happiness is accidental and not at our disposal, but freedom is effective "independent of external causes that determine it" (1993b: BA 97–98, p. 81, BA 99–100, pp. 82–83). A human being does not act morally because he or she hopes for happiness – "If *eudaemonia* (the principle of happiness) instead of *eleutheromania* (the principle of freedom for inner legislation) is set as the foundation, the consequence will be euthanasia (the soft death) of all morality" (1997: AIX, p. 506) – but because he or she follows the principle of freedom of inner legislation. This entails that morality has been robbed of the foundation on which it could ground itself, that is, the hope for the remuneration for moral action that would arrive at some point. And by implication the pursuit of happiness loses the justification that was derived from its link to morality. Simmel (1989: p. 253) called this the "mutual independence of ethicality and happiness." 'If our ethical action,' Simmel wrote, "were only a detour on the path to happiness, then the point of our freedom would show itself again interwoven with the dependence on the powers of being, without whose favors no happiness could be complete."

The expulsion of the concept of happiness from moral philosophy has its counterpart in the eviction of happiness out of the realm of the political. For Kant, freedom has taken the place of happiness as the goal of politics – a concept driven further by romanticism, although setting out from the non-*eudaimonistic* ways of reasoning in transcendental philosophy. Kant's categorical imperative expels the concept of *eudaimonia* from some strands of philosophical discussion.

Redemption, Happiness, and Political Order

The emerging social sciences have started out from this rupture and have largely accepted it. In his theory of religiosity and morality, Durkheim reinterprets happiness and identifies it in religious experience, in moments of 'collective effervescence,' of self-transcendence and loss of self. Happiness is seen as the experience of being-one-with-oneself or of being submerged in the world, as a "feeling of strengthening" (Durkheim, 1981: p.

291), as the subjective 'oceanic feeling,' which Freud (1994) considers without any comprehension. Simmel, too, considers spiritual salvation (*Seelenheil*) as a state in which complete harmony with the world has been achieved, a state that shows the full liveliness and inner touchability of the perceived, the immediate being (Simmel, 1995). "Happiness, as a relation of transcendence, thus has two fundamental forms. It exists as the experience of either *oneness* or *otherness*, as the dissolution of all difference, or as the apprehension of, and unconditional surrender to, absolute difference" (Ferguson, 1992: pp. 11–12). Such experience articulates social integration and, again, connects the individual with the other and with a 'holy' collectivity, the ideal community of justice.

Within the main line of critical theorizing, that is, in Theodor W. Adorno and Max Horkheimer, the subjectivization of happiness is further radicalized. The foundational character of the aporias that result from the dualism of individual and society is rejected. Instead, the joint attack of liberalism (*bourgeois* ideology) and capitalism is held responsible for the destruction of the link between freedom and happiness.

Happiness is privatized in 'administered society' and under the reign of 'culture industry,' and it becomes the expression of societally determined false consciousness. Due to the horror of the circumstances, individual happiness becomes nothing but the dreadful arrangement of a petty-bourgeois idyll with its swollen sentiment. The *bourgeois* promise of happiness arising from property and possession becomes under conditions of inhumanity a curse. The promise of the commodity turns into pale appearance; in the totality of objectivizable socioeconomic relations, the connection between the individual, happiness, and society is interrupted and the promise of happiness only admitted as aesthetic experience (Adorno). But, within the same critical tradition, and by appropriating critically Freud's reflections on the pleasure principle and the reality principle, Herbert Marcuse (1955/1966) aims at developing a social theory that elaborates on a conception of possible happiness and permits the critique of both, the societal circumstances as well as the empirically existing conceptions of happiness. "The concept (of happiness) denotes a more-than-private, more-than-subjective condition; happiness is not in the mere feeling of satisfaction but in the reality of freedom and satisfaction" (Marcuse 1955/1966: pp. 103–104). The concept of happiness has to be liberated from bourgeois conformism and relativism; even the singular human beings cannot be 'judge of their own happiness' under these circumstances. It is precisely the task of critical analysis to show the 'possibility of a happier real constitution of humanity' beyond the existing 'false happiness.'

In another line of critical thinking, Walter Benjamin turns political time, directed toward happiness, into the key element of his philosophy of history. "The image of happiness … is tainted by time through and through … In other words, the imagination of happiness resonates inalienably with the one of redemption" (1991a: p. 693). Happiness is here not in the (past) event, but in its possibility, to which a 'weak messianic power' is given; it is recognizable only in its being missed historically (1991a: p. 694). "The order of the profane has to erect itself with the support of the idea of happiness" (1991b: p. 203) – and in the *Angelus Novus*, Benjamin finds the image for history in which the past, that which is complete (misfortune and misery), and the future, that which has remained incomplete (happiness), get reverted and in which misfortune and misery turn into something incomplete hoping for redemption (1991c: pp. 588–589). Ernst Bloch, too, reinstates the old connection between the individual, passion, and society; happiness becomes again an inalienable part of human being. "Because hope's grounding in the human drive for happiness is too difficult to be destroyed; and too evidently has it always been the engine of history" (1978: I, p. 515). Happiness, thus, even though pushed into the private realm since Kant, persistently returns into the political realm – as 'redemption,' 'the principle of hope,' as 'emancipation,' 'undamaged life,' and, in the version of existentialist philosophy, as 'authenticity.'

During the past few years, happiness has not only become the object of dubious empirical quantitative research on levels of satisfaction, but also again a theme of social philosophy, partly by referring to classical liberalism, partly also by returning to ancient traditions. Under terms such as justice, the good life, and self-realization, the question about concepts of the good life in modernity and the societal conditions under which happiness can unfold is again raised (Thomä, 2003; Thomä et al., 2011). The attempt is, thus, renewed to locate happiness not only in an 'accomplished' relation of the individual to her- or himself, but also in relation to others and to a just social order.

Hannah Arendt already held a view of political happiness, of 'public happiness,' that could not be equated with the obligation of the state to care for the welfare of its citizens (such a view of *bonheur*, in contrast, is, in her view, coresponsible for the loss of freedom in the course of the French Revolution). In the American Revolution, however, the connection between 'public happiness and political freedom,' which is an 'inalienable part of the structure of a republican community,' could be maintained at least for some period (Arendt, 1994: p. 178). The new connection between happiness and freedom occurs in the sign of plurality and a public sphere as guardians against both dangers; that namely substantive conceptions of happiness could suffocate freedom or that abstract and atomized freedom empties out any conception of happiness at all.

Drawing on the classical contract theories by John Locke and Jean-Jacques Rousseau and situating himself in relation to Immanuel Kant, John Rawls develops a 'theory of justice' (1971) for modern, pluralistic, and democratically constituted societies. For Rawls's theory, the 'right' enjoys primacy over the 'good,' since value-pluralistic societies will be able to agree only over a minimum set of foundations for what is right, but not over what is good. Rawls, thus, renounces any attempt to formulate a substantive theory of the good life. The starting point of his considerations is the hypothetical construction (the 'intuitive thought') of a society as a fair system of cooperation between free and equal persons. Since these considerations provide the general political framework for the 'good life as justice and fairness,' a human being can for Rawls be called "happy … during those periods when he is successfully carrying through a rational plan and he is with reason confident that his efforts will come to fruition" (Rawls, 1971: p. 550). Rawls ties his theory of justice to a critique of utilitarianism. For him the well-being of people does not depend on the degree to which individual preferences are realized. It is

important only that people are provided with the basic means to the same amount. As Martha Nussbaum, however, points out, Rawls did not consider what people do with these goods, to what they are enabled, and whether the space of enablements that thus opens up is not marked by striking inequalities.

Nussbaum (1990, 1993) herself resorts to Aristotle to sketch those political foundations that are to enable all people to lead a good life. She does not advocate any liberal relativism, but rather a universalism, based on an anthropological conception, that refers to needs and capacities which all people across all divides of culture, class, and sex have in common. Such basic needs constitute moral demands; they are an inalienable part of ethics and moral philosophy. At the same time, Nussbaum's perspective aims at pushing back the primacy of reason in moral philosophy, since moral principles had hitherto mostly been anchored in human reason and, as feminist critique remarked, had been considered predominantly an exclusive male capacity (Gilligan et al., 1989; Held, 2005; Noddings, 1984). Her ethics of virtue attempts to counteract the insufficient regard for the particularity of situations in moral theories that are based on general principles. In addition, it aims at integrating emotional dimensions into ethics. To define the concept of virtue more precisely, and not merely to understand it by recourse to rules, a 'superior instance' needs to be found; for Nussbaum this is a theory of the good. Starting out from the 'basic structure of the human form of life' (mortality, corporeality, cognitive abilities, practical reason, sociality, etc.), she develops an 'open list' of the basic capacities of human beings and of the good. She herself characterizes the list as 'vague,' which means that it is open for concretization in each specific cultural context, and then puts specific demands toward politics. The objective of measures taken by the state is that they enable the citizens to choose a good form of leading their lives, to develop their capacities, and to live in accordance with practical reason and with their social ties.

In his attempt at clarifying the relations between a moral life and a good life, Seel (1995) similarly defends a "universalism of the good," which is not linked to particular forms of society. This universalism, however, is no essentialism that claims the existence of values independent of human volition or raises anthropological facts to the status of values or norms. Seel develops a position that he calls "reflexive *eudaimonism*" and asks what it entails, from the viewpoint of different people, "to sensibly lead a succeeding life" (p. 10), defining a 'good life' formally on the basis of moral respect, social recognition, and political legitimacy. The incarnation of good human life is a "life, open to the world and self-determined, the moral and legal protection of which includes a respect for all individuals who are able to have a (however determined) good life" (p. 11).

'Happiness,' 'the good life' are, thus, always also tied to sociocultural circumstances and the social *imaginaire* (Friese, 2011). It remains the task of philosophy as well as of the social sciences to think the – political – conditions under which a good life and happiness stay open as a possibility. Happiness as the relation to oneself, to others, and to the community thus, belongs to reflection, to experience, and to the dream (Mauzi, 1969).

Eugenics as a Basis of Population Policy

Abstract

This article considers the eugenic basis of population policy by reviewing national and international developments during the twentieth century. Examples from the history of eugenics are invoked in order to contextualize this topic both diachronically and conceptually.

Population policy refers to control of human population by legislation or other official means. It involves setting goals for such population parameters as total size, the maintenance of demographic stability, and birth and mortality rates. Population policy includes both privately funded programs, such as the contraception campaign promoted in India in the 1950s by the Rockefeller Foundation, and publicly funded programs such as those promoted throughout the Third World by the United States Agency for International Development (USAID). There are also state-controlled population policies, such as the natalist programs in Ceausescu's Romania, the sterilization of Roma women in Czechoslovakia and, more recently, of indigenous women in Fujimori's Peru as well as China's current restrictive family planning. Often, there are religious aspects involved in certain population policies such as the Catholic Church's traditional opposition to contraception and abortion. Finally, there are social and economic factors that shape population policy, most notably voluntary sterilization in Brazil.

In the twentieth century, population policy has often been associated with eugenics. The term 'Eugenics,' derived from the Greek *ευγενής*, or *eugenes*, and was first coined by English statistician Francis Galton (1822–1911) in his book *Inquiries into Human Faculty and Its Development* to refer to one born 'good in stock, hereditarily endowed with noble qualities' (Galton, 1883). As an intellectual and social movement, eugenics came to mean, in the words of one of its strongest American supporters Charles B. Davenport (1866–1944), "the science of human improvement by better breeding" (Davenport, 1910). For both Galton and Davenport, better breeding implied improving the biological quality of the human species by the scientific principles of heredity. Eugenicists wanted to develop policies that dealt not only with the quality of the population but also its growth. In this sense they sought to increase the reproductive rate of that segment of the population deemed to be biologically (meaning genetically) well-endowed (positive eugenics), and limit or prevent the reproduction of that segment of the population deemed to be biologically inferior or degenerate (negative eugenics).

Eugenics was essentially based on biological, or genetic determinism (the idea that genes determine more of what a person is like, both in personality and in physical traits, than environment; eugenics took the side of 'nature' in the long-standing nature–nurture debate). The largely ignored model of heredity Gregor Mendel (1882–1884), the Moravian monk, had published as early as 1866 – subsequently known as the system of Mendelian inheritance – challenged the theory of blending inheritance (namely that an offspring's makeup constituted a blend of his or her parents' traits). Mendel's research on the nature of inheritance proved that an offspring's genetic structure was not simply a synthesis of that of the parents, but that particular genetic traits could be either dominant or recessive, and that these were passed on in accordance with statistical laws.

By the time of World War I the Mendelian principles of heredity were being applied with great success to the breeding of many varieties of animals and plants; it also revolutionized theories of human genetics and evolution. It was in this atmosphere that eugenics flourished. It was hailed as a scientific solution to recurrent social and biological problems. If alcoholism, criminality, pauperism, and feeblemindedness were all determined by genes, then the way to eliminate these problems would be to prevent the reproduction of those individuals thought to carry those genes. While eugenicists were concerned with the inheritance of physical abnormalities such as hemophilia, color blindness, brachydactyly (shortened digits), and debilitating diseases such as Huntington's chorea (all recognized to be genetic prior to 1910), they were ultimately more interested in human behavioral and personality traits – including mental ability, mental illness, 'moral degeneracy,' and criminality, to list only a few – all of which they claimed were genetically determined to a significant degree.

Encouraged by the reception to Galton's ideas in Britain, the Eugenics Education Society was established in 1907 in London. Other countries followed this example and in Scandinavia, for instance, a Swedish Society for Race Hygiene was formed in Stockholm in 1909. American eugenicists had established the Station for Experimental Evolution at Cold Spring Harbor as early as 1904, followed by the Eugenics Record Office in 1910. The French Eugenics Society was established in 1912. In Central Europe, Czech, Austrian and Hungarian societies were established in 1913 and 1914. Also in 1914, an Italian Eugenics Committee convened at the Roman Society of Anthropology. By then, the German Society for Racial Hygiene and the German League for National Regeneration and Heredity, both established in 1905, were intensely involved in disseminating eugenics to the general public, both at home and abroad, as illustrated by the Hygiene Exhibition organized in Dresden in 1911. However, it was in the United States, Britain, the Scandinavian countries, and Germany where eugenics as an

intellectual and social movement reached its greatest strides and from eugenicists' point of view, greatest ideological and political results (Adams, 1990).

Eugenic Research: Its Aims and Problems

Following Galton's research into the genealogy of illustrious British individuals, the family pedigree chart became the main analytical means for displaying and analyzing data on the inheritance of one or another trait. Information was collected from among a group of relatives, and it was displayed as a family pedigree chart, emphasizing that traits ran in families and thus how heredity influenced many behavioral, personality, and mental traits. The American eugenicist Charles Davenport claimed, for example, that thalassophilia, or 'love of the sea,' was a sex-linked Mendelian recessive appearing in the families of prominent US naval officers (Davenport, 1919). That the condition must be sex-linked was clear to Davenport, since in pedigree after pedigree only males in the various families he studied became naval officers. Such simplistic Mendelian arguments were then extended from individuals to large groups as a way of explaining the differences between racial, ethnic, and national groups.

Because of their concern with the apparent rise in 'feeblemindedness,' eugenicists embraced the nascent psychometric movement (intelligence testing) starting as early as 1912. In that year, Henry H. Goddard (1866–1957) administered a version of the French Binet–Simon test to immigrants arriving at New York's Ellis Island (Zenderland, 1998). Although the Binet–Simon test was intended to measure only an individual's mental functioning at a given point in time, Goddard and a host of psychometricians in the United States and Europe considered that it also measured innate, or genetically determined intelligence. Goddard coined the term 'feeblemindedness' (which he claimed was genetic) to refer to those people who scored below a given level (70) on his tests, and claimed that it was transmitted from generation to generation. It was also Goddard who carried out the famous study of the Kallikak family, showing what was presumed to be the hereditary effects of feeblemindedness and degeneracy (Goddard, 1912). For American eugenicists, the new mental tests seemed as a precise, quantitative tool for measuring an otherwise elusive, but fundamental human trait. Eugenically inclined psychometricians felt that the scientifically trained expert could at last solve with rational and scientific methods the social problems that muddle-headed politicians and social workers had been unable to solve during the preceding century.

A major problem with eugenic research was that it quickly fell behind the work being done by geneticists in laboratories throughout the world. By the 1920s many geneticists had come to recognize that genes (collectively, known as the organism's genotype) interact with one another (a phenomenon known as epistasis) and with the environment to produce any given trait (the organism's phenotype). The interaction of genes with one another and environmental factors (for example, temperature, drugs, diet) was found to alter the gene's expression in profound ways, yielding a variety of alternative phenotypes from the same genotype. Even the position of a gene along the length of its chromosome turned out to affect the way that gene is expressed. This malleability, or plasticity, of the genotype–phenotype relationship meant that even knowing the genotype of the offspring at conception did not provide a certain means of predicting the phenotype. While they adopted much of the exciting new work in genetics in the 1920s and 1930s, it is apparent that many eugenicists did not really understand it fully, or take to heart its implications for their social programs.

Eugenics and the Control of Reproduction

One of the aims eugenicists across the world shared was the desire to allegedly improve the population's quality by controlling its reproduction. Eugenic sterilization is one of methods used toward achieving this goal. In the United States, Harry H. Laughlin (1880–1943) was particularly active in lobbying for the passage of a number of state eugenic sterilization laws in the 1920s and 1930s. Indeed, Laughlin drew up a 'Model Sterilization Law' that served as a prototype from which each state could derive its own modified version (Laughlin, 1922). Although the earliest such laws had been passed before World War I, the majority was established during the interwar period (Reilly, 1992). Eugenic sterilization was aimed specifically at those individuals in mental or penal institutions who, from family pedigree analysis, were considered likely to give birth to 'socially defective' offspring. Sterilization could be ordered only after a patient had been examined by a eugenics committee, usually composed of a lawyer or family member representing the individual, a judge, and a doctor or other eugenic 'expert' (Reilly, 1992). Between 1907 (when the first such law was put into effect in Indiana) and 1941, over 38 000 eugenic sterilizations were performed in the United States, with California leading all other states (Reilly, 1992). By the early 1960s, the number had risen to some 60 000. The most famous of the sterilization cases in the United States was that of Carrie Buck in Virginia. When Virginia passed its eugenic sterilization law in 1924, a test case was arranged the next year to determine if the law was constitutional. Buck vs. Bell was tried in 1925 in the Virginia Circuit Court (Lombardo, 1985). When the lower court ruled in favor of the law, an appeal was sent to the Supreme Court of the United States, where Justice Oliver Wendell Holmes wrote the majority report. In upholding the lower court ruling, Holmes made his oft-repeated assertion: "Three generations of imbeciles are enough."

In Europe, the debate on eugenic sterilization focused on two aspects: what social and medical categories would be subjected to sterilization, and what legislative forms such policies would require, namely, whether they would be voluntary or compulsory? In 1928, the Canton of Vaud in Switzerland authorized the sterilization of those suffering from hereditary mental diseases and those deemed feebleminded. A year later, the Danish Sterilization Law was introduced. Sterilization was contingent upon the medical diagnosis provided by a physician and upon the consent of the individual, the family or the legal guardian. A Committee for Legalizing Eugenic Sterilization was formed in Britain in 1929, and a bill for voluntary sterilization of mental defectives was introduced to Parliament in 1931. The campaign was, however,

unsuccessful as British eugenicists were divided over which preventive methods was most efficient, sterilization or institutional segregation. Amidst the growing acceptance of negative eugenics amongst Christian states in Europe and beyond, Pope Pius XI's issued the Encyclical on Christian Marriage, *Casti Connubii* in 1930. The encyclical castigated the prevention of 'unworthy' life advocated by eugenicists both as an expression of excessive secularization and of the state's interference in the individual and family's private sphere. The opposition of the Catholic Church notwithstanding, eugenic sterilization remained a popular method of population control during the 1930s: it was also adopted by the Baltic states and was discussed in Eastern Europe in countries like Hungary, Romania, and Poland (Turda and Weindling, 2007).

It was, however, in Nazi Germany after 1933 that eugenics served as the main basis of population policies (Weiss, 1990). The Law for the Prevention of Progeny with Hereditary Diseases was officially announced on 14 July 1933, and became effective on 1 January 1934. In theory, it stipulated that "anyone with hereditary diseases may be rendered sterile by surgical means, when, according to medical experience, it is highly probable that the offspring of such person will suffer from severe inherited mental or bodily disorders." In practice, however, several medical categories were outlined, namely: (1) hereditary feeblemindedness; (2) schizophrenia; (3) manic-depressive insanity; (4) hereditary epilepsy; (5) Huntington's chorea; (6) blindness; (7) deafness; and (8) severe hereditary malformation (Gütt et al., 1934). Chronic alcoholics were also subjected to the law. Hereditary Health Courts were established in 1934 to supervise the implementation of sterilization.

Other countries, such as Sweden, emulated the German sterilization model and introduced compulsory sterilization of persons suffering from insanity, feeblemindedness, and other mental disorders in 1934. Similar legislation followed in Norway (1934), Finland (1935), and Estonia (1936), allowing for compulsory sterilizations on medical, social, and eugenic grounds. In other countries, like France, for example, the Nazi model of compulsory sterilization was viewed with suspicion due to its totalitarian and racial aims. Akin to some Italian and Romanian eugenicists, French eugenicists also distinguished between a 'Latin eugenics' understood to focus more on improving the social environment and education, and an 'Anglo-Saxon eugenics' seemingly preoccupied with negative prevention, selective breeding, and racial protectionism.

The empowerment of the state to enact population and eugenic policies was not restricted to the United States, Nazi Germany, or Fascist Italy. Demand for a eugenically predisposed state was vast and extensive, coloring the outlook of eugenicists of various political orientations, such as anarchists in Spain, socialists in Britain, feminists and Social Democrats in Germany and Sweden, and health educators in Turkey. A number of Fabians, including luminaries such as G.B. Shaw (1856–1950) and H.G. Wells (1866–1946) argued that an effective and comprehensive eugenic program could best be pursued in a socialist state. This was also an idea entertained by the American eugenicist Herman J. Muller (1890–1967), who believed that Stalin would be the architect of a new humanity, one in which eugenic rationality would reign supreme.

Eugenics as Population Policy

A qualitative population policy, able to accompany quantitative measures, was vital for the success of eugenics; moreover, this task was a national duty for both the state and the eugenicists, especially during the interwar period. It was World War I that brought population policy (known as *Bevölkerungspolitik* in the German-speaking countries) and eugenics together. Examples include the German and the Austrian Societies for Population Policy and the Hungarian Society of Racial Hygiene and Population Policy. In the wake of the dramatic demographic changes brought about by the war, population experts reviewed the relationship between marriage and illegitimate children, the importance of nutrition and the distribution of arable land and unemployment. All these guidelines and suggestions for practical measures in the field of eugenics and population policy were supposed to provide Europe's much-needed demographic growth. In many respects, Italy's fascist welfare program served as the model. The National Organisation for the Protection of Motherhood and Infancy, established in 1925, emphasized positive incentives to increase the quantity and quality of the population. Fascist demographers and eugenicists attempted to unify maternal and child welfare with rural development schemes, offering in fact a nationwide program of social and biological engineering.

These programs gradually took over during the 1920s and 1930s, placing natalist ideas of demographic growth and large families at the center of eugenic thinking. In each European country, eugenic population policies assumed various overtones according to national circumstances. In the United States, the biologist Raymond Pearl (1879–1940) claimed that eugenicists had focused too much attention on the quality of offspring from particular (usually 'degenerate') families, and had lost sight of the equally important issue of the rapid birth rate of the biologically 'degenerate' at home and abroad. In a series of scientific and popular articles he began to articulate the ideology of population control. While critical of much of the current eugenic propaganda, Pearl did not disavow basic eugenic principles. He simply emphasized the importance of quantitative as well as qualitative considerations. In Central and Eastern Europe, for instance, it was the state that was particularly dedicated to population policies, such as those of resettlement, meant to strengthen the racial character of those regions perceived to be either depopulated or under threat by other ethnic groups.

By the year 1940, eugenic population policies became the norm in Europe, as exemplified by the Bulgarian Law for the Protection of the Nation, the National Fund for the Protection of Family and Population in Hungary, the Law for the Protection of the Race adopted by the regime of Widkun Quilsing in Norway, or the French Law for the Protection of Mothers and Children. Undeniably, these laws advocated the same political protectionism of the dominant racial group and the exclusion of ethnic minorities, especially Jews, but they also, like in the Bulgarian and French cases, introduced sanitary screening and mandatory premarital examination, aiming at a general biotypological investigation of the nation. Facing World War II, the eugenic rhetoric of the 1940s intensified in its racial tone. Eugenicists in Hungary and in France, for instance, profited from this ideologically favorable environment to establish racial institutes, like the Hungarian Institute for National

Biology (established in 1940) and the French Foundation for the Study of Human Problems (created in 1941).

Maintaining the nation's demographic potential thus became of prime political importance alongside instruments for eliminating the 'dysgenic groups,' be they defined socially or ethnically. By investing the state with the powers for protection of the family and the nation, a new eugenic ethos was devised, whereby ideas of social and biological improvement were combined in innovative ways. On the one hand, social hygiene, public health, and family welfare were based on the broad concept of eugenics; on the other, political reform and economic development became coterminous with the preservation of the race.

In the aftermath of World War II, the United States emerged as a contender for global power, inheriting the mantle of international economic and political involvement that had previously been carried by the British and, to a lesser extent, the French. In 1952, President Dwight D. Eisenhower formed a blue-ribbon panel, headed by David Rockefeller of the Chase National (later Chase-Manhattan) Bank, to evaluate the future prospects for US industrial and commercial expansion around the world. In the same year, the Rockefeller Foundation organized a conference in Williamsburg, Virginia, under the direction of John D. Rockefeller III, to study what Pearl had highlighted as the 'population problem.'

The blue-ribbon panel concluded that the single greatest obstacle to US industrial expansion (meaning access to cheap raw materials, labor, and ultimately markets) was the rapid population growth occurring in most Third World countries. Such population increases not only required the retention of more of countries' raw materials (including agricultural products) at home, but also fueled local revolutionary movements aimed at eliminating foreign control. Not surprisingly, the Williamsburg conference called for the formation of an organization to look into methods for controlling population growth. Out of this meeting came the proposal for establishing the Population Council, with Rockefeller funds and John D. III himself as President. Frederick Osborn (1889–1981), still Secretary of the American Eugenics Society at that time, soon took over as Council President, running both organizations out of his office in Rockefeller Center in New York.

One of the first major projects of the Council was the funding of investigations of various forms of birth control, including the intrauterine device (IUD), and eventually, to the first birth-control pill (Watkins, 1998). Initial trials in Puerto Rico beginning in April 1956, led to field studies in other Third World countries such as India and Pakistan. One of the major incentives used to promote these studies was the economic benefits that would accrue to families that had fewer children. That such pilot population control movements encountered considerable resistance in the countries where they were introduced, suggested that local people saw the matter quite differently. The programs provided a lesson in the cultural and social components of reproductive life. For many in agricultural, Third World countries, large families were the only way to insure some manner of economic survival. Children worked on farms at an early age, and thus more than earned their 'keep,' while large families often provided the only form of old-age insurance in countries that lacked programs for the elderly. This lesson is still one to be learned by leading political and many environmental and conservation groups, who continue to advocate population control as the major agenda for Third World countries. Today, for example, the USAID, a branch of the State Department, devotes a significant portion of its budget to its Population Office. Programs emerging from USAID support population control programs in over 20 Third World countries.

Criticism of Eugenics, 1925–50

Almost from the beginning, many of the basic premises of eugenics were brought under critical scrutiny by scientists and the general public alike. Among the first and most important critics from the biological side was Thomas Hunt Morgan (1866–1945), the *Drosophila* geneticist at Columbia, in 1933 the first recipient of the Nobel Prize for work done in genetics, and one of the earliest members of the Committee on Animal Breeding of the American Breeders' Association (a Committee that had taken on itself organizing the first eugenic activities in the United States). In a personal letter sent to his close friend Davenport in 1915, Morgan resigned from the Committee, explaining that the claims being made on behalf of eugenics were exaggerated beyond what any scientific evidence could support (Allen, 1978). Although Morgan did not criticize eugenics in print at that time, from 1925 on, starting with his book *Evolution and Genetics* (Morgan, 1925) he publicly chastised eugenicists for lumping many mental/behavioral conditions together under a rubric like 'feeblemindedness' and treating them as if it had a single underlying cause. Especially critical, he noted, was the fact that personality and social traits were the most malleable of our characteristics, and hence the most difficult in which to tease apart the relative contributions of heredity and environment:

> The important point is that mental traits in man are those that are most often the product of the environment which obscures to a large extent their inheritance, or at least makes very difficult their study. (Morgan, 1925)

The pedigree charts on which Mendelian analyses were based, were also strongly criticized by Morgan and others as giving the impression of tracing genetically determined transmission when, of course, they equally well could be interpreted as showing culturally determined effects:

> The pedigrees that have been published showing a long history of social misconduct, crime, alcoholism, debauchery and venereal disease are open to the same criticism from a genetic point of view; for it is obvious that these groups of individuals have lived under demoralizing social conditions that might swamp a family of average persons. It is not surprising that, once begun from whatever cause, the effects may be to a large extent communicated [socially] rather than inherited [genetically]. (Morgan, 1925)

In other words, pedigree charts do not separate 'nature' from 'nurture.'

Other geneticists followed suit. Raymond Pearl also voiced public criticism of eugenicists' claims, especially those

regarding the supposed biological inferiority of various racial and ethnic groups (Pearl, 1927). Along with his colleague Herbert S. Jennings (1868–1947) at Johns Hopkins University, Pearl felt that propagandists like Laughlin, Madison Grant, and others made claims that went far beyond any reasonable evidence (Barkan, 1992). Jennings devoted the better part of the ensuing decade (after 1924) to lecturing all over the United States about the dangers of oversimplified version of eugenics. Muller, a student of Morgan's, and subsequently himself to become a Nobel laureate in genetics, also delivered a searing attack on 'old style' eugenics at the Third International Eugenics Congress in New York City in 1932. Muller, who still harbored strong eugenic beliefs, argued that until the economic and social environment could be equalized it would be impossible to know how much of any individual's 'social inadequacy' was due to heredity and how much to environment (Muller, 1933). Much of feeblemindedness might be due to poor maternal diet during pregnancy or during the early years of childhood, or to maternal drug and alcohol use; although these effects might appear at a superficial glance to be genetic, they had nothing to do with defective germplasm. English mathematician and sometime eugenics critic Lancelot Hogben (1895–1975) made one of the clearest statements at that point of time about the oversimplified concept of genetics that informed much of the eugenics movement: "No statement about a genetic difference has any scientific meaning unless it includes or implies a *specification of the environment* in which it manifests itself in a particular manner" (Hogben, 1933: p. 14).

In 1934, a special blue-ribbon committee of the British government published the Brock Report (named for its chairman, Laurence B. Brock, head of the Joint Committee on Mental Deficiency), outlining difficulties in determining the relative contribution of genetics to mental deficiency. Among others, the Committee included Ronald A. Fisher, himself a staunch eugenicist but also one of the world's foremost statisticians and population geneticists. The Brock Report agreed with the criticisms of eugenics put forward a few years earlier by Lionel Penrose, who had demonstrated that the category of 'feeblemindedness' was ill-defined; was used carelessly and indiscriminately to cover a host of mental problems that were caused in many cases by disease and social deprivation; and for the most part little was known of the genetic cause of mental disability (Kevles, 1985).

An even more comprehensive and devastating critique of the whole range of eugenic claims was published by the American Neurological Association in the mid-1930s, just a few years after the appearance of the Brock Report (Committee of the American Neurological Association, 1936). Work for the book was funded by the Carnegie Foundation through the New York Academy of Sciences. Like the Brock Report, the findings of the Committee found that by the mid-1930s abundant evidence threw into doubt such well-accepted eugenic beliefs as: (1) The vast number of mental and moral/personality traits are genetically determined, (2) Environment (upbringing) plays a relatively minor role in the development of mental and personality traits, and (3) Sterilization is the most effective means of reducing the frequency of socially inadequate behavior in future generations.

The Committee of the American Neurological Association supported many of the general conclusions of the Brock Report. Citing the work of Morgan, Jennings, and others in the United States, and that of J.B.S. Haldane in England, the authors argued that we do not know 'enough about the mental diseases and the effects of the social structure to manipulate in a successful way the procreation of the race' (Committee of the American Neurological Association, 1936). The level of genetic knowledge was too slight to formulate any social policies or carry out any specific manipulations guaranteed to alter the genetic basis of future generations. More specifically, it was found that eugenicists consistently downplayed the role of the environment in the development of mental and behavioral problems, even when it seemed obvious that social and economic conditions must be playing a highly significant role. Herbert S. Jennings made the same point, emphasizing that 'environment' included the internal, cellular, as well as external environment in affecting how genes were expressed. Even if a person is clearly shown to have a genetic defect, as in hereditary thyroid deficiencies, Jennings argued, the condition can be treated with dietary and/or drug supplements, which can restore normal function. A whole host of human anatomical and physiological conditions that were clearly genetic did not need to be debilitating or limiting to the individual, according to Jennings, because in many cases we possess the technological means to restore, or at least compensate for, the genetic defect. Genetics, according to Jennings, was not destiny (Jennings, 1927). For eugenicists, however, it was, and this remained one of the underlying assumptions of hereditarian thinking from the past to the present.

On the eve of World War II (literally 1 week before), another strong criticism of eugenics emerged as the 'Geneticists' Manifesto,' a document signed in early August 1939, by a group of geneticists assembled in Edinburgh at the VIIth International Congress of Genetics. Among the major initiators were J.B.S. Haldane (1892–1964) and Lancelot Hogben, and H.J. Muller. The Manifesto put forth Muller's argument that from a genetics point of view, as long as vast disparities in wealth and access to resources continued to exist in western societies, no claims could be made about the relative contribution of heredity over environment to human mental capacity and social behavior (Chase, 1977). They condemned racialist thinking, especially the attempt to rank races with respect to one another on the basis of genetic worth. The geneticists who initiated and signed the Manifesto were among the most well known and respected workers in the field during the twentieth century.

Despite these severe criticisms, eugenics continued to thrive in the Scandinavian countries and especially in Nazi Germany (between 1933 and 1945). After passage of the sterilization laws in 1934, the Nazi government enacted the infamous Nüremberg Laws in 1935, prohibiting marriage between Aryans and Jews and other 'non-Nordic' groups. Doctors were required to report to the Ministry of Health cases of what they deemed to be hereditary diseases among their patients, and after the large-scale deportation to concentration camps, became involved in a variety of genetic experiments on twins. All in all, German population experts carried out eugenic principles further than in any other country of Western Europe

or North America, notwithstanding the condemnation from other European eugenicists.

In the period after World War II overt criticisms of eugenics as the basis for population policy became more widespread. Revelation of Nazi atrocities committed in the name of eugenics played an important role in this change of attitude. In addition, hard-line eugenicists such as Davenport, Laughlin, Grant, and others on the American scene were retired or deceased by the end of the war, and were replaced by what historian Daniel J. Kevles has dubbed moderate, or reform eugenicists.' Although it might be questioned how really 'reformed' these eugenicists were, it is clear they were more knowledgeable about the nuances of what traits genes might and might not control, less overtly racist, and more modest in their claims for what eugenics might accomplish. Partly because of the criticism, it was difficult for the field of human genetics to get a fresh start after the war, and many geneticists shied away from dealing with human heredity (Kevles, 1985: 193ff; Ludmerer, 1972). Textbooks and other writings on human genetics were careful to distance themselves from old style eugenic thinking (Ludmerer, 1972). Laurence H. Snyder's *Human Genetics* (1951), for example, stated clearly that "[w]e should hesitate at accepting without careful analysis the claims and recommendations that are present in a large portion of the eugenics literature." An understanding of the historical development of the eugenics movement, Snyder went on to say, would suggest, "why professionally trained geneticists, on the whole, have given relatively little support to eugenic theories and programs" (quoted in Ludmerer, 1972). Anthropologist and prolific popular writer Ashley Montague echoed the same feeling in his 1959 *Human Heredity* when he wrote that much unfortunate public policy – by which he meant immigration restriction and state sterilization laws – had been based on "the ill-considered, prejudiced, and unscientific judgments of the late Harry Laughlin … Madison Grant … and Charles Benedict Davenport" (Montagu, 1959: pp. 25–26). And, in 1960, the American Medical Association came out with a report, 'A Reappraisal of Eugenic Sterilization Laws,' that called into question virtually all the assumptions of the old eugenic movement. In the decisive debates over the excesses and disastrous effects of eugenic dreams of perfectibility (particularly since the 1950s), the problematic connotations of population policy for the individuals and communities involved are ever-present. Understanding the eugenic basis for population policy is, therefore, essential in both its historical and comparative perspective.

Eugenics as an International Movement

Abstract

Eugenics, the study of the social forces under human control that work to insure the best possible genetic future, was first coined as a term by Francis Galton in 1883. It became a widespread movement throughout Europe (England, France, Germany, and Scandinavia), North and South America (the United States, Canada, Cuba, and Brazil), Russia and the former Soviet Union, and Asia (China and Japan). Most supporters of eugenics were upper middle-class professionals and wealthy elites who saw the high birth rate of lower socioeconomic groups as a threat to social order and the progress of 'civilization.' Eugenicists in most countries sought to influence legislation on such reproductive issues as birth control and sterilization, and immigration restriction. Eugenics movements differed from country to country in terms of the theories of heredity on which they were based (Mendelian and Lamarckian) and local cultural influences such as religion and family structure.

The term eugenics, derived from the Greek ευγενεσ (eugenes) was first coined by English mathematician and geographer Francis Galton (1822–1911). In his book *Inquiries into Human Faculty and Its Development* eugenics refers to "one born 'good' in stock, hereditarily endowed with noble qualities" (Galton, 1883: p. 24). Eugenics was considered to be the human counterpart of scientific animal and plant breeding.

In his book, Galton lays out all the dimensions that came to characterize eugenics as an ideology and social/political movement during the first half of the twentieth century. These were as follows: (1) adherence to the methods of selective breeding as applied to the improvement of the human species; (2) a strong belief in the power of heredity in determining physical, physiological, and mental (including personality) traits; (3) an inherent ethnocentrism and racism that included belief in the inferiority of some races or groups and superiority of others (a view extended to ethnic groups and social classes as well); and (4) belief in the power of science, rationally employed, to solve social problems, including ones so seemingly intractable as pauperism, crime, violence, urban decay, prostitution, alcoholism, and various forms of mental disease, including manic depression and 'feeblemindedness' (retardation).

It took some time after Galton first propounded the idea for eugenics organizations and activities to emerge around the world, but by the time of World War I (1914), eugenics had become a truly international movement. Thus, the standard historical view of eugenics as a largely British, American, and German phenomenon is inaccurate. Eugenics developed in a variety of national contexts with a wide range of ideological and political programs (Adams, 1990b: pp. 4–6, 1990d: pp. 217–231). The earliest eugenics movements were founded in Germany in 1904, in Britain in 1907, and in the United States in 1908–10. Other eugenics movements appeared around the world shortly thereafter: in Western Europe between 1910 and 1920: France, Spain, Hungary, the Scandinavian countries (including Finland), Russia, Latin America (Cuba, Brazil, and Mexico), Canada, Africa (particularly South Africa), and Asia (China and Japan). While eugenics in its modern form – that is, viewed as a branch of genetics – clearly originated in the West, its spread around the globe gave it an international flavor that from the start retained a common core of scientific and political beliefs while developing local variations. Eugenicists themselves were consciously internationalists, arguing that like all sciences, eugenics knew no national boundaries. Recently, various scholars have applied what is called 'social movement theory' to understanding the common global processes (economic, social, scientific, and cultural transfer) that helped to foster the rise of eugenics and other such movements simultaneously in a number of different countries and national contexts (Barrett and Kurzman, 2004). Despite this international profile, however, it was in Western countries such as the United States and, of course Germany under the Nazi regime (1933–45), that eugenics as an intellectual and social movement reached its greatest strides, and from eugenicists' point of view, enjoyed its greatest ideological and political success.

The international character of eugenics is reflected in the three major international congresses, at which eugenics enthusiasts gathered literally from around the world. The first was held in London in 1912, while the second and third were held in New York (the third congress was held at the American Museum of Natural History) just following the sixth International Congress of Genetics, in 1932. Papers and photographs of exhibits from the second and third congresses fill several impressive volumes.

Although eugenics is often thought of as a politically conservative movement, globally its supporters came from widely divergent political backgrounds. Some, like Charles B. Davenport, Harry H. Laughlin, and Madison Grant in the United States, and Eugen Fischer in Germany, were reactionary, while others, such as Britain's J. B. S. Haldane, the United States' H. J. Muller, or Russia's Aleksandr Serebrovsby, were influential left-wing eugenicists who held socialist or even communist views (Paul, 1984: p. 567). Left-wing eugenicists were not necessarily egalitarians, however, and few envisioned a society in which all people were truly 'equal.' Their model was a meritocracy based on inherited biological worth. It was the reliance on a rational, scientific approach to matters of reproduction and family planning that attracted many, including some liberals, to the eugenic ideal (Kevles, 1986).

Background: Degeneration Theories and the Rise of Eugenics (1890–1914)

In both the West and the East, the late nineteenth century saw, for different reasons, a widespread belief that the human species was in various phases of deterioration and decline (Paul, 1995). Much of this pervasive pessimism came from observations in the social and political arenas. British eugenicists were particularly concerned with the high fecundity and presumed inherited mental degeneracy of the urban working class, particularly those labeled as 'paupers' or (in Britain) the 'residuum.' By contrast, American eugenicists were more concerned with the number of 'feebleminded' who appeared to be filling the prisons and insane asylums in the wake of urbanization and industrialization after 1865 (the US Civil War) and with the genetic deficiencies of the 'new immigrants' around the turn of the century. In Germany, various racial and ethnic groups were thought to harbor an undue proportion of mentally ill, psychotic, psychopathic, and psychiatric members. In France and Brazil, where ideas of the inheritance of acquired characteristics held more sway than in most other countries, public health measures, rather than reliance on selective breeding, were seen as the most effective means to combat degeneracy. In Asia, general theories of degeneration spread with the encroaching influence of Western imperialism from the 1860s onward. The inability of the Asian populations toward off imperial penetration or intra-Asian rivalries was seen as partly a result of scientific and technological backwardness and of physical and cultural weakness in the face of the Western onslaught.

Eugenics and Scientism

Eugenics throughout the world was viewed as the application of rational and 'modern' scientific principles to the solution of age-old social problems (Pickens, 1968). Eugenicists and many of their supporters had a high regard for science and technology, symbols in the Western countries of the triumph of enlightenment and rationality, and of modern capitalist control over, and exploitation of, nature for human gain. The goal of science was to predict and control, an ideology extended to society at large. The period in which eugenics developed was globally one of great economic, social, and political instability: two major world wars; the dissolution of the great empires of Europe in the wake of rebellions abroad; rapid industrialization in the West, especially the growth of heavy industry; and urbanization, all of which contributed to the rise of such problems as alcoholism, prostitution, crime, mental illness, and social unrest. In the major Western countries, organized labor gained great strength, leading to increased and bloody conflicts in the period 1890–1940. Communism made major gains during the period, with the Bolshevik Revolution in Russia, the organization of Workers' Councils that took over several cities in Germany after the Armistice in 1918, and with the expansion of such groups in the United States as the International Workers of the World (the IWW, or 'Wobblies') who carried out a successful general strike in Seattle and other areas of the northwest United States in 1919.

Outside of Europe, similar, sometimes related, historical events led to similar responses. Latin America underwent convulsive economic and social change in the wake of the decline of Spanish and rise of North American colonialism. In Asia, the struggle in China and Japan toward 'modernization,' inter-imperialist rivalries culminating in the Sino–Japanese War of 1894–95, and the Russo–Japanese war of 1905, all stemmed from growing expansionism related to trade, and control of raw materials and markets between East and West and within rising industrial powers, like Japan, in Asia itself. As in the West, science and technology in Asia were associated with modernism and economic advancement.

As a supposed new 'science,' eugenics meshed well with modernist ideology. Eugenics was based on what was thought to be the cutting-edge research in a new field (genetics): it was mathematical, experimental, rigorous, predictive, and purported to apply the principles of science to the solution of previously intractable social problems. Worldwide, it provided an incentive for academically trained practitioners (geneticists) to join the new managerial class that was beginning to apply highly trained expertise to everything from organizing factory production lines, offices, and schoolrooms, to 'scientific' agriculture and not least, human reproduction. Applied to society, eugenics became part of the ideology of 'social engineering' that was replacing the older notion of *laissez faire* associated with social Darwinism. It was not enough to let nature take its course: scientifically trained social engineers had to step in and direct that change along rational lines. Eugenically, this change involved the guidance of human reproduction to ensure that only those with good heredity passed on their genes to future generations. Eugenics was viewed as the 'control of human evolution.' Eugenicists argued that to control heredity at the source was to be efficient – to prevent problems before they occurred, rather than let them happen and then deal with the consequences. In various forms – either as proposed breeding and sterilization programs or maternal and other public health proposals, the efficiency argument dominated much of eugenic social rhetoric. In the United States, this collage of views and ideas was swept up into a somewhat heterogeneous movement known as progressivism. Progressives advocated the use of science to solve social problems, and embraced the efficiency movement of Frederick Winslow Taylor (1856–1915), which had been developed in the United States initially in an industrial context. Similar strains and arguments appeared in different forms in eugenics movements around the world.

Since other articles discuss various specific aspects of eugenics movements around the world (*see* Eugenics in Europe; Eugenics as the Basis of Population Policy; Eugenics, History of; Eugenics in Asia), this article will focus on the general nature and extent of international eugenics activities, comparing the similarities and differences among the various national movements.

British and American Eugenics, 1880–1940

British and American eugenics shared a number of intellectual and social concerns, as well as personal contacts (Kevles, 1986). The major importer of eugenics to the United States, Charles B. Davenport (1866–1944), spent part of the year from 1899 to 1900 with Galton and his protégé, Karl Pearson (1857–1935),

at University College, London, learning statistics and biometrics and gaining initiation into Galton's 'secular religion of eugenics.' American eugenics thus grew directly out of the vision that Galton, and later Pearson, developed. At the same time, American eugenics developed its own particular twists, especially its early acceptance of particulate, discontinuous, and Mendelian concepts of heredity, a relationship not shared by their British counterparts until the later 1920s.

Mendelism notwithstanding, American and British eugenicists shared the basic assumption that such traits as alcoholism, criminality, physical and mental 'defects,' socioeconomic position, and intelligence, were all biologically inherited, with the worse forms concentrated in the lower classes and among certain races. Horrified by the significantly higher birthrate of the lower classes, eugenicists in the United States and Britain argued that the observed decline in productivity and 'national efficiency' was due to the increasing number of less productive social defectives that were being born and were having to be cared for by the state. Eugenics was a 'scientific' approach to improving social efficiency. In Britain, Pearson's largely theoretical orientation to eugenics led him to warn eugenicists to avoid politics. Partly as a result, British eugenicists had much less legislative success than their counterparts in the United States (Kevles, 1986).

In several ways, the American movement followed a different trajectory from the movement in Britain. First, American eugenicists became strong advocates of psychometrics, the burgeoning new school of I.Q. testing, which took it for granted such tests measured an innate, unchanging mental function. While British eugenicists also assumed that mental ability was inherited, they did not employ the I.Q. (or other similar) tests to the same extent as in the United States. Second, leaders of American eugenics were from the start anxious to play a role in the public arena – in what today would be called formation of public policy. Eugenicists such as Harry H. Laughlin (1880–1943), Superintendent of the Eugenics Research Office at Cold Spring Harbor, NY, USA, translated eugenic principles into social action (Ludmerer, 1972). Eugenicists lobbied for passage of the Johnson–Reed Act (Immigration Restriction Act) in the United Sates Congress in 1924, while Laughlin designed a 'Model Sterilization Law' and eugenicists lobbied for the passage of eugenical sterilization laws in a number of states during the 1920s and 1930s. The first eugenical sterilization laws were passed in the United States (the first were passed in the state of Indiana, 1907), although by the mid-1930s, such laws were in place in a number of Western countries (Norway, Sweden, Finland, Germany, and Canada). Between 1907 and 1965, more than 60 000 people in the United States – mostly in state institutions for the feeble-minded, psychiatric hospitals, and prisons – were sterilized. Like their British counterparts, American eugenicists were highly motivated by the ideas of national efficiency and rational planning (Vecoli, 1960; Allen, 1986: pp. 255–260).

Eugenics on the Continent: Germany, Scandinavia, and France

On the continent, eugenics in Germany and Scandinavia shared many features in common, while France took its own, unique direction. The German and Scandinavian movements were based strongly on what has been termed notions of 'hard heredity' (i.e., that most mental and moral attributes are rigidly determined by genes at conception), and employed basic concepts of Mendelian genetics. While the ideology of Nordic and Aryan superiority was present in both movements, it represented only one strand, and not always the most prominent strand in eugenic thought prior to the ascendancy of the National Socialists in Germany in 1933 (Weiss, 1990). Ideologues of the German movement, such as Fritz Lenz (1887–1976) and Eugen Fischer (1874–1967), were racial purists, but during the Weimar years kept a 'subdued' profile on overtly racial issues. Because racial purity was a cornerstone of the Nazi regime, however, eugenics after 1933 became openly racist and pro-Nordic (Weiss, 2010).

A number of common ideological convictions characterized German eugenics from its pre-1900 days, right down through the 'final solution': (1) The conviction that *laissez-faire* capitalism was at heart dysgenic because it allowed individuals to reproduce at will, with no concern for the future well-being of society. (2) The belief that Germany's population was degenerating, as evidenced by the debacle of World War I, increases in labor unrest, and social problems such as alcoholism, criminality, prostitution, mental illness, and retardation. (3) A strong belief in the value of a managed society based on scientific expertise.

At the same time, several features distinguish German eugenics from its counterparts elsewhere: (1) More German eugenicists were drawn from the medical profession than in either England or the United States (Proctor, 1988). (2) During the Weimar Republic and later the Nazi regime, eugenics received far more government funding than in most other countries. German geneticists and eugenicists all held posts on important government advisory councils dealing with matters of eugenics and national health (Weindling, 1985, 1989: pp. 308–309). (3) A major feature of German eugenics was the subsequent role it came to play in the National Socialist government and the Holocaust, between 1933 and 1945.

Some historians have argued, cogently, that eugenics became so prominent and virulent in Germany because of the humiliation of defeat in World War I and the exacerbating terms of the Treaty of Versailles. Among the factors leading to military defeat, eugenicists argued, was the nation's national degeneracy, the influences of racial impurity, declining birthrates among the intelligentsia, and economically prosperous, and the anti-eugenic policies associated with socialist egalitarianism (Meineke, 1963: pp. 30–34; Mosse, 1964: pp. 237–240). Worsening economic conditions due to reparations payments and loss of the mineral-rich Ruhr Valley, gave, among average Germans, added weight to arguments for improving national efficiency by eliminating what the Nazis termed 'useless eaters' or 'lives not worth living' (Weindling, 1989: pp. 305–310). Under national socialism, eugenics eventually became the scientific rationale for euthanasia and genocide.

The Scandinavian countries, including Finland, had well-entrenched eugenics movements by the 1920s, those in Norway and Sweden being the largest and most politically successful. Scandinavian eugenics showed much of the character of the other Western movements: an emphasis on efficiency, commitment to legislative action, and a strong

pro-Aryan and Nordic stance (Broberg and Roll-Hansen, 1996). In the period between 1910 and 1925, Scandinavian eugenics was characterized by a strong belief in the superiority of the Nordic races, and thus displayed a nationalist and racist undertone. These took the form of social legislation, particularly the passage of eugenical sterilization laws (Denmark's law was passed in 1919, Norway's in 1934, and Sweden and Finland's in 1935). The rates of sterilization varied considerably: between 1935 and the 1960s, Sweden sterilized over 62 000 people – an astonishing figure for a country whose total population at the time was less than 7 million (Roll-Hanson, 1996: p. 263). Eugenics achieved its greatest political success in Sweden, although the most vocal international voice from Scandinavia was that of Jon Alfred Mjøen (1860–1939), a Norwegian pharmacist turned eugenic activist. Although shunned by many scientists in his own country for his racist views, Mjøen was viewed as a major theoretician by eugenicists in Sweden and Denmark. Nonetheless, Scandinavian eugenics as a whole never adopted the virulent Nordic racism found among Nazi elements in Germany. As advanced welfare states, the Scandinavian countries also couched their eugenics proposals in terms of 'national efficiency.' Hit hard by the same economic problems faced by other countries during the interwar period, and especially after 1929, the Scandinavian countries were seeking to reduce state expenditures wherever possible, and the supposedly hereditarily defective became an even more likely target.

Eugenics in France

The French, as other Europeans, harbored a growing concern about what was perceived as the degeneration of society, in France's case associated with a declining birthrate and loss of military hegemony on the continent after the Franco-Prussian war of 1870. French eugenics also embraced as strongly as elsewhere the idea of rational management by scientifically trained experts, especially in areas of social policy. Like other countries during the same period, France was beset with a variety of economic, social, and political problems that called for sweeping changes in both public attitudes and government policy (Thomson, 1960: pp. 173–186). Before, but especially after, World War I, class struggle accelerated in such publicly visible forms as large-scale strikes (Tilly et al., 1975: pp. 71–76). Like Germany, eugenics in France was strongly supported by members of the anthropological, medical, and public health professions. French eugenics differed from that in England, the United States, and Germany, however, in three very important respects: (1) The presence of a strong Enlightenment tradition of radical social theory and practice that laid greater emphasis than elsewhere on environmental, as opposed to biological, determinants of human personality and behavior. (2) Concomitant with their emphasis on the environment, French biologists maintained a strong commitment to neo-Lamarckian concepts of heredity, that is, the direct inheritance of environmentally induced variations. Consequently, eugenicists in France did not emphasize Mendelian genetics and Darwinian natural selection. (3) The strong influence of the Catholic Church, especially with regard to matters of reproduction, caused French eugenicists for the most part to avoid advocating measures such as contraception, sterilization, or abortion to deal with actual or potential defectives (especially after the Papal Bull, *Casti connubi* in 1930, which condemned eugenical sterilization). The effect of the church position was to widen an already existing division within the eugenicists' ranks: between liberal and conservative and between pro- and antisterilization forces. Thus, French eugenicists never attained the unity necessary to lobby effectively for specific eugenic measures at the legislative levels.

Illustrative of French eugenics is the work of Just Sicard de Plauzoles (b. 1872), a doctor, a reformer, and Secretary of the Venereal Disease Commission of the Ministry of Health. He was the author of two highly influential books, *Tuberculosis* (1900) and *Motherhood and the National Defense against Depopulation* (1909). As a public health official, Sicard joined the French Eugenics Society in 1922 under whose auspices he gave a popular course of lectures every year on 'social hygiene' at the Sorbonne, aimed at medical, health, and government officials. Sicard's brand of eugenics was cast in the terms of preventive medicine and public health, analogous to programs for public sanitation. Like many eugenicists, he was a devotee of the industrial efficiency movement, carrying his analogy to the point of referring to human beings as "work-producing machines" and eugenics as the technique for "procreating, perfecting and utilizing man" as "human capital" (Schneider, 1990: p. 89). In this vein, he also stressed the importance of quality over quantity: increasing the birth rate of superior human beings, like high-quality machines, would ultimately be more cost-effective. The working classes, he felt, were showing signs of degeneracy due to their higher birth rate combined with defective heredity. His eugenics was thus much more class based than race based. In addition to his influence through lecture course and writings, Sicard was also a legislative activist, helping to sponsor a bill in the Chamber of Deputies in 1932 calling for the repeal of a 1920 law that forbade the sale or advocacy of contraceptive devices (the bill did not pass).

Thus, while French eugenics shared with the British, German, and Scandinavian movements a desire to improve the overall biological quality of the population, it differed in several important respects: (1) The French eugenicists' theory of heredity – non-Mendelian and neo-Lamarckian, or 'soft heredity' – clearly set it apart from most of the other countries. (2) The emphasis on soft heredity thus led the French to focus more attention on such environmental factors as health care in general and maternal health care in particular, sanitation, nutrition, and public health programs. (3) The strong presence of the Catholic Church stymied any strong eugenic legislation such as compulsory sterilization laws; under these circumstances, environmental approaches were more logical and practical. As a coherent movement, then, eugenics in France never attained the high degree of organization and political effectiveness that it enjoyed in the United States or, later, Nazi Germany.

Eugenics in Russia

The development of eugenics in Russia occurred in a turbulent period in that country's history, framed by the onset of World War I (1914), the Bolshevik Revolution (1917), and the

subsequent attempt to fashion a new society based on distinctly different ideologies and social practices. As in other countries, eugenics made its entrance into Russian society in the first decade of the twentieth century along with Mendelian genetics, both of which were brought from Europe by Russian biologists studying abroad, such as Nikolai Kol'tsov (1872–1940) and Iurii Filipchenko (1882–1930). The eugenics movement took shape starting around 1920 when Filipchenko and other committed Bolsheviks saw eugenics as the perfect fit to postrevolutionary Soviet ideology: it was the application of a rational and materialist theory to a vision for a new kind of human society. Although vigorous at first, the eugenics movement as such in the Union of Soviet Socialist Republics was rather short-lived, flourishing only from 1920 through the early 1930s, when it came under increasing attack by the Communist Party as racist and elitist and was eventually disbanded (Graham, 1977: p. 1145; Adams, 1989: pp. 881–882).

Although Russian biologists had begun to develop a strong Mendelian research program by 1914, the advent of the war, the revolution of 1917, and the ensuing civil war retarded further development of most scientific work until after 1920. The decade between 1920 and 1930, in which Russian genetics and eugenics expanded rapidly, can be divided conveniently into two periods: 1920–25 and 1926–30. The eugenics of the first period was modeled on movements in the West, particularly Germany, with which Russian scientists traditionally had close ties. In the second period, Soviet eugenicists attempted to create their own socialist eugenics based on the Marxist principles of historical materialism and a scientific approach to society (Graham, 1977: p. 1145).

In the aftermath of the revolution, Mendelian genetics began to play an important role in Soviet agriculture. Resources were severely limited and the famines of 1920 and 1921 impressed on Lenin and other leaders the importance of the scientific breeding for increasing food production in the future. As in other countries, eugenics gained prominence by coat tailing on the expansion of Mendelian genetics. From there, it seemed only natural to extend genetic principles to the scientific breeding of humans as well.

Concrete form was given to Soviet eugenics in 1921 when its two most important organizations were formed: the Russian Eugenics Society and the Bureau of Eugenics of the Soviet Academy of Sciences (Graham, 1977: p. 1146). The Eugenics Society, composed of both biologists and laypersons was given a small state subsidy, and was oriented toward political activism. The Bureau, composed of professional geneticists, was fully subsidized by the state, and was more oriented toward research and scholarly publication. Workers at the Bureau were particularly concerned to insulate the new science of eugenics from entanglement in political matters. Members of the Society, by contrast, were eager to inject genetic ideas into the social and political arena and saw no conflict between eugenical principles and socialism (Graham, 1977: p. 1146). This approach commanded particular attention in a Marxist state, where a conscious policy of wedding theory and practice was considered the cornerstone of the new politics.

Like their counterparts in other Western countries, many of the younger members of the Russian Eugenics Society were alarmed about the dysgenic effects of war and declining birth rate among the intellectual and educated classes. This topic received much attention in the work of M. V. Volotskoi (1893–1944) in a 1923 book, *On the Sexual Sterilization of the Hereditarily Defective* (Adams, 1990: p. 175). Based on a survey of the state sterilization laws in the United States, Volotskoi argued for large-scale sterilizations of the unfit to improve the genetic character of the Russian people. Volotskoi's ideas met with considerable opposition, however, on moral as well as scientific and political grounds. Since birth rate had fallen disastrously in recent decades, proposals for birth control or sterilization were viewed as dysgenic. Thus, negative eugenic programs never developed a significant following in the Soviet Union.

A more viable option for pursuit of eugenic goals was the widespread belief in neo-Lamarckian inheritance. Like biologists and eugenicists in France and Germany, many in the Soviet Union adhered to some form of neo-Lamarckism. Volotskoi, for example, argued that neo-Lamarckism alone allowed for the rapid improvement in human biological qualities that eugenics called for. If the gene was as fixed an entity as classical Mendelian genetics suggested, there was little chance of creating the new Soviet human being by eugenical means. Through significant changes in the social and economic environment, however, Volotskoi saw the opportunity to achieve eugenic ends in a manner consonant with a Marxist worldview.

However, Mendelian geneticists such as Filipchenko and Serebrovsby pointed out that the social environment could affect the germplasm in a negative as well as positive way, so that the proletariat and peasantry, subjected for so many past generations to poor environment and nutrition would be likely to have inferior germplasm, a conclusion distasteful to most Marxists (Adams, 1990c: p. 177). Thus by the mid-1920s, Mendelian genetics and its associated eugenic ideology were already headed on a collision course with the neo-Lamarckians that was ultimately to have disastrous consequences for Russian biology in general, and genetics in particular. It is the debates around this issue that characterize the second period in the development of Soviet eugenics (1925–30).

In response to the Communist Party's call for implementation of the first Five Year Plan in 1928, Aleksandr Serebrovsky (1892–1948) along with the young medical geneticist Solomon G. Levit (1894–1938) proposed that if the Soviet Union were cleansed of all its hereditary defectives, the Five Year Plan could be achieved in two and a half years (Adams, 1990c: p. 180). Serebrovsky made his plan concrete by proposing the use of methods of artificial insemination recently developed for animal breeding to ensure the most eugenical matings unencumbered by the problem of forced marriage or intercourse. It was such proposals that brought eugenics, and its associated Mendelian genetics, under further scrutiny. An article published in 1925 in one of the major journals of Marxist theory launched a pointed attack on eugenics claiming that eugenicists emphasized biological determinants of human behavior to the total neglect of social and economic factors (Graham, 1977: p. 1150). Sounding a neo-Lamarckian refrain, the article suggested that attention to the human environment would go a lot farther toward improving human mental and physical health than eugenics.

At the same time, the pressure to produce rapid results for agricultural improvement produced a schism between the more theoretical geneticists and government and party leaders. Mendelian genetics seemed to yield few immediate results, and its association with eugenics made it appear to be an example of bourgeois elitism and racism (Joravsky, 1970: p. 30; Levins and Lewontin, 1985: p. 164; Adams, 1990c: p. 183). In response, however, Mendelian geneticists such as Kol'tsov and Serebrovsky argued that the best long-range results would be obtained by allowing geneticists to continue working on simple model organisms like *Drosophila* rather than the much more complex and experimentally difficult agricultural organisms like cows and chickens. Many Soviet geneticists, like their counterparts elsewhere, had adopted a technocratic approach, working in their specialized laboratories rather than in the fields and breeding farms (Adams, 1990c: p. 182). Government and Party officials increasingly saw these attitudes as bourgeois and elitist. Serebrovsky was attacked in 1930 for being overly technocratic and biologistic by treating human beings as resources like coal and gas (Adams, 1990c: p. 184). Largely as a result of these developments, in 1930 the Communist Party launched an attack on Mendelian geneticists as bourgeois experts and their associated eugenics claims were officially outlawed. A number of major Soviet geneticists/eugenicists were demoted or lost their positions and the Russian Eugenics Society was disbanded in that year. By 1931, the Soviet eugenics movement as such had ceased to exist in any organized form.

Although Mendelian genetics itself was beginning to come under attack in the early 1930s by neo-Lamarckian agronomist Trofim D. Lysenko (1898–1976) and his followers, it remained a viable research program well into the 1930s in such institutions as the Maxim Gorky Research Institute of Medical Genetics (Adams et al., 2005: pp. 251–252). However, the association of Mendelian genetics with eugenics along with its opposition to neo-Lamarckism led ultimately to the claim that geneticists had imported Fascist ideas into Soviet science, and to the arrest (and in some cases execution) of its leading proponents (Adams, 1989: p. 883). By the late 1940s, Lysenko's hereditarian claims became official Soviet policy and Mendelian genetics (and geneticists) banned. It would take Soviet genetics at least two more decades to recover.

Eugenics in Latin America

The existence of significant eugenics movements in non-European and non-Anglo-Saxon contexts has been ignored by historians of science until quite recently (Adams, 1990b; Stepan, 1991). Eugenics movements in Latin America rose to prominence between the world wars and commanded considerable attention within the worldwide eugenics community. Interest in eugenics stimulated some of the first genetics courses in Latin American universities, and was often an important factor in child welfare, maternal health, infectious disease, and immigration legislation in the various countries (Stepan, 1990: p. 110). Eugenics was also discussed vigorously at various Latin American scientific and public health conferences, as well as being the focus of two specific Pan-American conferences of its own (Cuba in 1927 and Argentina in 1934). A special eugenics society, the *Fédération International Latine des Sociétés d'Eugénique*, was founded in 1936 under the leadership of Corrado Gini, a well-known Italian eugenicist and president of the Italian Society of Genetics and Eugenics. The *Fédération* held one international congress, in Paris in 1937. Moreover, leaders of eugenics movements in other countries expressed keen interest in the developments in Latin America. Not only Gini in Italy, but also Davenport and Laughlin in the United States offered considerable encouragement to fledgling societies in Cuba and Mexico.

One of the most important differences between Latin American and European eugenics was the political economy of neocolonial 'underdevelopment' in which most Latin American countries existed in the first decades of the twentieth century. Although just beginning to experience industrialization and urbanization after World War I, Brazil, for example, was still largely an agricultural country with an impoverished rural population that was illiterate and dominated by the Catholic Church. Much of the land was held as plantations by local family oligarchies and foreign investors who produced more for export than for local consumption. The country was ruled by a tiny elite largely educated abroad. Biology, such as existed, was housed only in medical schools and agricultural stations. Historian Nancy Stepan has pointed to the highly mixed racial composition of most South American countries as a factor differentiating the Brazilian eugenics movement from that in Europe or the United States (Stepan, 1990: p. 11).

Four specific factors helped to make eugenics attractive in the period after 1920 in countries such as Brazil (Stepan, 1990: pp. 112–114): (1) A rising new nationalism and sense of independence gained from the war experience. The collapse of Germany, whose science and culture had been so much admired in Brazil and other Latin American countries before the war, generated a new sense of independence about what Latin Americans could accomplish on their own. (2) There was increased recognition of 'the social question,' that is, the appalling poverty and poor health of the working and peasant classes. After 1915, the combination of poverty, massive migrations, and immigration from abroad (particularly Italy) produced a radicalization of politics. A large-scale strike in 1917 in São Paolo, Brazil, was met with brutal repression by the government and industry leaders. Under these circumstances, eugenics began to play the same role as it had in the United States and Britain: a means for breeding out the biological defectives who were claimed to be the cause of such disruptions. (3) Growing enthusiasm for science, and particularly biological science, as a way toward economic and social progress, especially in the area of public health, had been imported into Latin America from Europe and the United States. As in both France and Germany, eugenics in Latin America was easily incorporated by an expanding medical profession eager to assert its own power and expertise in generating new or reformed public health policy. (4) Finally, the widespread racial intermixing (between people of Indian, African, and European descents) that characterized most Latin American countries had two very different effects in Latin America: on the one hand, as in Europe, it raised the specter of race suicide and impending degeneracy; on the other, large numbers of South Americans had mixed ancestry, thus making

racial classification so fluid that the sharp distinctions made in European countries and the United States never developed with the same intensity.

With the exception of Cuba, most early eugenics programs in Latin America were derivative of those in Europe, particularly France (Stepan, 1990: p. 114). This meant that they often adopted version of neo-Lamarckian rather than Mendelian concepts of heredity, and for a variety of local reasons were also much more concerned with improvements in sanitation, nutrition, and public health. Indeed, most of the members of local eugenics organizations were drawn from the medical or other related professions.

Because it had one of the largest and most well-developed eugenics movements, Brazil has become one of the best studied examples of eugenics in Latin America. As a dependent colony even after liberation in the earlier part of the nineteenth century, Brazil was ruled by an elite of mostly Portuguese ancestry that shared the general European racial views regarding indigenous peoples or those with mixed ancestry in the New World. And with the abolition of slavery in 1888, many of the ruling elites feared the degenerative effects of racial miscegenation. At the same time, the colonial powers needed to deal with issues of tropical disease that affected their administrators and military personnel, as well as local populations.

Thus, in the earlier phase of Brazilian (and other Latin American) eugenics movements, the focus was on environmental improvements which, under a general neo-Lamarckian framework, was expected to yield long-term hereditary, as well as short-term health and medical benefits. This does not mean, however, that traditional ideas about biological heredity were absent. For example, at one of the early organizing meetings of what was to become the São Paulo Eugenics Society in 1917, the medical doctor Renato Ferraz Kehl (1889–1974) opened with a description of Galton's 'new science of eugenics,' and proceeded to discuss several policy proposals, including the desirability of prenuptial physical and mental exams and a proposed revision to current Brazilian law allowing consanguineous marriages.

After starting from this more anthropological and public health perspective, by the 1940s a new generation of eugenicists had adopted Mendelian genetics and began to apply it to formulate Latin American eugenics policies. Greatly stimulated by the visit of American geneticist Theodosius Dobzhansky (1900–75) to Brazil in 1943, eugenicists in Latin America, unlike their US or German counterparts, used genetics to argue that miscegenation, like crossing different strains of animals and plants, could produce superior, not inferior or 'mongrel,' lines. The Mendelian eugenicists thus came into conflict with the neo-Lamarckian eugenicists, creating a division within the ranks of the movement as a whole.

Mendelian geneticists and eugenicists were particularly prominent in agricultural schools, and like their counterparts elsewhere were particularly concerned with issues of inbreeding and outbreeding and their potential effects on the viability of hybrid crosses. Mendelian critics of neo-Lamarckism, and its effects on the progress of eugenics, included two highly influential scientists: the anthropologist Edgar Roquette-Pinto (1884–1954), Director of the National Museum of Anthropology, and the biologist Octavio Dominguez (n.d.) at the Agricultural School of Piracicaba (near São Paulo). Roquette-Pinto had enormous prestige in scientific circles and his promotion of Mendelian theory was particularly important in developing that side of Brazilian eugenics. He claimed in 1929 at the First Brazilian Congress of Eugenics that what he considered the 'confusion' between eugenics and sanitation/public heath would be cleared up by the time of the second congress, and eugenics could then begin to make great strides in Brazil. Dominguez was a major writer of textbooks that promoted an orthodox view of Mendelism, much of it derived from Galton, Pearson, Davenport, Castle, and other Anglo-American writers. He was also a member of both the American Genetical Association (originally American Breeders Association) and the Eugenics Society of London. Although not free of views of human hierarchical worth, on the whole Mendelian geneticists and eugenicists in Brazil tended to be far less overtly racist than their counterparts in Britain and the United States. In the face of largely foreign-dominated economic, political, and social expansion, however, racism, particularly in the form of and marginalization of the continent's black and Indian populations, remained one facet of Brazilian and other Latin American eugenics movements.

The Latin American experience illustrates the quite different path that eugenics could take in an environment far removed from the centers of scientific advancement, one in which scientific ideas were derived largely from outside. The strong orientation of most Latin American eugenics to personal and public hygiene, as well as to nutrition and medical care, clearly reflects the existence of widespread poverty, malnutrition, and disease (hookworm, malaria, and yellow fever) among the vast and largely rural populations. With economic and health problems of such magnitude, issues of race and race mixture were less central among Latin American eugenicists than among their counterparts in the industrialized world.

Eugenics in Asia

Scholars studying the history of modern Asian science have pointed out that eugenics had a role to play in many of those societies. Moreover, it was not merely Western eugenics imported and imposed on Asian society *carte blanche*. In both China and Japan, eugenics fitted well with movements for the increased promotion of science and technology associated with conscious attempts at what was called 'modernization.' Mendelian genetics was introduced to both China and Japan in the early decades of the twentieth century by Western scientists who traveled to Asia, as well as by Asian scientists who came to work in laboratories in the West. Unlike their Western counterparts, eugenicists in both China and Japan relied less on a formal, organized set of genetic theories, promoting eugenics primarily as a 'modern' way of dealing with traditional problems. In addition, there appears to have been no strong, organized neo-Lamarckian tradition in China or Japan as existed in the major European movements, so when eugenics was introduced along with Mendelian genetics, it did not encounter the same sort of theoretical resistance as elsewhere. However, in China after the communist revolution in 1949, Lysenkoist views became an important ideological foundation for the study of heredity, and thus a conflict between Mendelian and

neo-Lamarckian views became part of the scientific debates well into the 1950s and 1960s (Schneider, 1988: pp. 28–29).

Chinese eugenics, when it was introduced in the 1920s and 1930s, was perhaps unique among all nations in that few if any well-trained scientists, including biologists, were participants. Rather, it was a movement of intellectuals and journalists (Schneider, 2003: p. 132). The most active eugenicist with any scientific background in this period was Pan Guangdam (1898–1967), who had studied biology, but never worked as an active biologist. He promoted a kind of 'positive eugenics,' which appeared to raise fewer moral issues than negative eugenics (Schneider, 2003: p. 139). For Chinese intellectuals and 'progressives,' eugenics became a way of grounding the calls for social and economic reform in science, a view akin to the Western principle of rational, social control. While not relying on Lamarckian notions of inheritance of acquired characteristics, during the 1920s and 1930s Chinese eugenicists emphasized the importance of education, public health, and other social measures, along with limiting family size. There was relatively little in the way of statistical or genetic research carried out by eugenicists in Republican China.

As elsewhere, eugenics in China was particularly supported by the rising professional middle classes, whose ideas were in various ways an amalgam of imported Western views and traditional Chinese notions of race and class. Despite the lack of explicit genetic input, as historian Frank Dikotter has argued, eugenic and racial thinking permeated much of Chinese culture from the latter part of the nineteenth century through the first half of the twentieth century (Dikotter, 1992).

After the advent of the communist regime in 1949, traditional eugenics was attacked as racist and fascist as it had been in the Soviet Union, and a few earlier proponents of eugenics recanted their views (Schneider, 2003: p. 139). By the 1970s, however, population growth and calls for population control policies were increasing. This culminated in 1978 with the One Child Law, which raised considerable concern both inside and outside of China. Whether the policy has strictly eugenical implications is highly debated, but it is clearly one of the most drastic reproductive control policies developed by any country in the past or present.

In Japan, during the early decades of the twentieth century, eugenics was linked more closely than in China with both Mendelian genetics as well as movements for birth control, sex education, and public health. In this context, conditions such as venereal disease, tuberculosis, alcoholism, and leprosy were all considered inherited and eugenicists argued they should fall under the same regulations as those governing public health matters. The difference is due in large part to the much closer connection between Western (particularly German and American) biologists and those in Japan. Here too, as in the West, eugenics was seen as a scientific means of combating social and moral degeneracy. In 1935, Japanese eugenicists were successful in getting the Imperial Diet to pass a Racial Eugenics Protection bill, which favored the sterilization of hereditarily mental defectives. A sterilization law based on the German 1933 law (in turn based on model laws in the United States) was drafted in 1936, but a fully comprehensive eugenics law was not adopted until 1940.

Ironically, although eugenics was on the wane in the West after World War II, it became more prominent in Japan during that same period. A full-scale Eugenical Protection Law was passed in 1948, allowing for involuntary sterilization of those with undesirable, supposedly inherited traits. By 1996, over 16 000 such operations had been carried out. This law was very much influenced by the experience of US geneticists, particularly those involved with the Atomic Bomb Casualty Commission, a joint effort between Allied (mostly United States) and Japanese scientists to investigate the medical and genetic effects of high-energy radiation from the atomic blasts in Hiroshima and Nagasaki. Some of these geneticists had, or had once had, eugenical sympathies. In turn, many major Japanese geneticists had been educated in the United States in the 1920s and 1930s when eugenics was in its heyday. Eugenics in Japan therefore bore a stronger resemblance to its Western heritage than did eugenics in China.

Conclusion

Although the term eugenics was used worldwide, eugenic movements in various countries were shaped by local economic, social, political, and cultural factors, and thus differed from one another in substantial ways. It has become clear that, as a movement, eugenics was not monolithic. Although tied to rigidly hereditarian Mendelian genetics in the United States, Scandinavia, and somewhat later in England and Germany, eugenics was more aligned with neo-Lamarckian views of inheritance in France, Latin America, and the Soviet Union.

In their orientation toward various social issues and proposed solutions, eugenicists also varied considerably from country to country. In some, such as the United States, Scandinavia, and Germany, concern with racial issues played a prominent role – indeed the Nazis claimed the 'Third Reich' was based on the concept of the 'racial state.' In these countries, concern with the ill effects of race crossing was widespread, while in countries such as Brazil, race mixture was considered by some eugenicists actually to be a source of biological improvement (appealing to the concept of hybrid vigor). For British eugenicists, the supposed degeneration apparent among the lower classes was the counterpart of the supposed inferiority of racial and ethnic groups in the less developed countries. In all three cases, it was the economically dispossessed who formed the focal point of eugenicists' fears, and the targets of their programs.

Eugenics movements also differed widely in the social policies on which they focused. In those countries such as France, Brazil, and to some extent the Soviet Union, where a more neo-Lamarckian view prevailed and where the medical profession was more actively involved in eugenics, proposals tended to promote environmental reforms, particularly with regard to public health. In those countries such as the United States and Britain, and especially Germany after 1933, where more strictly Mendelian views were predominant, segregation and/or sterilization of supposed 'defectives,' as well as immigration restriction, were more commonly proposed solutions.

It should be pointed out that the scientific basis for eugenical claims – that complex behavioral, personality, and mental traits are inherited in a 'hard-wired' fashion, and particularly that they follow Mendelian patterns of inheritance – has never found strong empirical support. Most eugenicists had a simplistic understanding of Mendelian

genetics, and persistently ignored environmental inputs into determining social traits. Various geneticists in the West, such as Thomas Hunt Morgan (1866–1945) and Herbert Spencer Jennings (1868–1947) strongly criticized the genetic claims on which eugenics was based, but their public critiques came late in the movement (starting in the mid-1920s) and appear to have done little to stop it.

Underlying all the differences, eugenics movements worldwide shared a concern for efficiency, the ideology of scientific management, the role of middle-class experts in establishing social and political policy, and a strong faith in science. Underlying all this, however, in almost all eugenics movements, was a powerful undercurrent of apprehension about the supposed degenerating biological quality of the human species. Eugenics programs, from California to the Baltic Sea, were aimed at increasing the biological worth of the human species by applying the latest genetic and medical knowledge. That such knowledge was often incomplete or flawed ultimately brought the eugenic tree to bear a bitter fruit.

Eugenics in Asia

Abstract

Eugenics not only spread in Europe between the two World Wars, but also developed a large following in Asia, in particular, in China and Japan. Eugenics was promoted by social reformers who believed that the reproductive rights of individuals should be subordinated to the rights of an abstract racial collectivity. These debates culminated in several eugenics laws in Japan after World War II, while the People's Republic of China passed eugenic legislation in 1995.

Eugenics, a term coined in 1883 by the English scientist Francis Galton, had its heyday during the first half of the twentieth century. Its proponents claimed that breeding principles such as assortative mating and artificial selection could improve the quality of human offspring. 'Positive eugenics' would ensure that individuals with above-average abilities would breed at a higher rate than ordinary people. 'Negative eugenics' would restrict the reproduction of inferior people, while those having subnormal abilities would have to be physically prevented from perpetuating their 'infirmities.' Mainline eugenicists assumed that intellectual capacity and behavioral traits were inherited and could not be significantly enhanced by education. Supporters included not only scientists, in particular geneticists, but also social reformers, journalists, and other members of the emerging liberal professions. Until recently, however, it was often assumed that eugenics only appealed to extreme right-wing thinkers or organizations in Germany or the United States, and the multifarious dimensions and extraordinary appeal of eugenics to individuals of very different social backgrounds, political convictions, and national affiliations was ignored.

Far from being a politically conservative and scientifically spurious set of beliefs that remained confined to the Nazi era, eugenics belonged to the political vocabulary of many modernizing forces between the two World Wars. It was not only supported by scientific societies, pressure groups, and political institutions in such different countries as France, Brazil, and Sweden, but it also developed a large following in Asia, in particular in China and Japan.

China

Eugenics in Asia is sometimes dismissed as a derivative manifestation of a more 'authentic' discourse in 'the West,' a misleading interpretation that can only impoverish our understanding of the complexities of cultural and intellectual encounters between population groups around the world. When the history of eugenics is explored in a variety of cultural, social, and political contexts, it resists any reductive explanation. As in European cultures, popular hereditarian notions – encapsulated in such sayings as 'like begets like' – helped the emergence and acceptance of eugenic ideas in Asia. Well before Darwin's time, experts in China had attained a sophisticated level of knowledge about selection and breeding, particularly in botany and in goldfish. On the other hand, many medical publications discussed in great detail ways of improving the physical quality of a line of descent while also highlighting the medical dangers to future offspring of careless reproduction. Patrilineal culture, in which reproduction was represented as a potentially dangerous process that should be carefully regulated in order to enhance the possibilities of engendering healthy male descendants, permeated traditional medical literature in imperial China. The individual, seen in relationship to the lineage, was held to be responsible not only for his or her own reproductive behavior, but also for the health of future offspring.

Interest in eugenics, however, only appeared in China in the wake of the reform movement of the 1890s, which openly sought to challenge imperial institutions and orthodox ideology. In search of wealth and power after the country's disastrous defeat against Japan in 1894–95, reform-minded scholars used Darwinian theories – inspired by Herbert Spencer and T. H. Huxley – to propose a radically new political vision based on faith in progress. Slogans such as 'survival of the fittest' and 'struggle for existence' became popular in China, a country increasingly represented as a 'race' that ought to be strengthened in its confrontation with imperialist countries. Public health, individual hygiene, even sexual behavior were targeted by reformers such as Kang Youwei and Liang Qichao as areas in need of state regulation in order to ensure the 'survival of the race' in a context of international competition. Only after the collapse of the empire in 1911 and its substitution by a republic, however, did eugenics develop a much wider following. Eugenics in republican China (1911–49), as in other countries during the interwar period, was not so much a clear set of scientific principles, as a 'modern' way of talking about social problems in biologizing terms: politicians with mutually incompatible beliefs and scientists with opposed interests could all selectively appropriate eugenics to portray society as an organic body which had to be guided by biological laws. Eugenics gave scientific authority to social fears and moral panics and provided an overarching rationale for welfare policies in China. Powered by the prestige of science, it allowed modernizing elites in China to represent their prescriptive claims about social order as objective statements irrevocably grounded in the laws of nature. Eugenics promoted a biologizing vision of society in which the reproductive rights of individuals were subordinated to the rights of an abstract organic collectivity.

Eugenic discourse had different meanings to different social groups in different contexts: it was appropriated and used in a variety of ways to accommodate radically divergent purposes and interests, being flexible enough to unite individuals or constituencies with contradictory agendas. One of the major dividing lines within eugenic discourse was that between a hard approach to heredity, based on genetics in Britain and Germany, and a soft approach combining an emphasis on the environment with hereditarian explanations.

The soft approach to eugenics was common in republican China as well as in other countries as diverse as Brazil and France. Professional groups in China campaigned for better public education in social hygiene and sexual health in the name of race improvement. Moreover, unlike researchers in countries that pursued a hard Mendelian approach, supporters of eugenics in China did not produce significant biological research or statistical studies. An emphasis on the virtues of education accounts for the relative absence in republican China of formal institutions, official organs, or professional organizations centered around the promotion of eugenic ideals. Rather than emanating from a solid organizational foundation, eugenic discourse was supported by a variety of voices in the social field: it attracted popular journalists, social reformers, medical writers, sex educators, university professors, and political ideologues, all attempting to promote medical knowledge and reproductive health for the sake of a more eugenic nation.

Eugenics was actively supported by members of the professional classes, in particular intellectuals, university teachers, sociologists, and biologists, and cut across most political positions, from the fascist core of the Guomindang to the communist theories of Chen Duxiu. Cheap textbooks on heredity and genetics explained to the public the dangers of racial degeneration. Primers, self-study manuals, cheap pamphlets, and 'ABC' introductions to mainline eugenics were published throughout the 1920s. Hereditary principles, endowing sex with a biological responsibility for future generations, were thought to further highlight the need for social discipline. In the 1930s, eugenic discourses became increasingly common in medical circles, 'degeneration' and 'racial hygiene' being the catchwords of the day. There is little evidence, however, to show that the widespread interest in eugenic ideas was translated into actual practice before the advent of a socialist regime, although some isolated cases, such as the execution of lepers by the police in Guangdong province in the 1930s, point to a more radical approach in questions of public health during the Nanjing decade.

The Second World War, followed by the civil war between the Communist Party and the Guomindang from 1945 to 1949, was the main reason why eugenic ideas did not achieve institutional form. The Committee for the Study of Population Policies, organized by the Ministry of Social Affairs in 1941, was the first official attempt to approach eugenics systematically. It recommended the segregation of physically and mentally handicapped persons from the normal population for what was called 'cultural advancement and racial rejuvenation.' Because people were thought to be unequally endowed, the report advocated a differential birth rate: 'Thus viewed,' said the report, "some individuals may have children, others not." The committee – whose members included Chen Da and Pan Guangdan – also encouraged the use of sterilization for the racial rejuvenation of the country and recommended that "(s)teps should be taken to segregate persons of hereditary defects, physical or mental, from the normal population" (Dikötter, 1998).

After the communist victory in 1949, the class bias of eugenics was systematically condemned, while genetics was denounced as 'bourgeois science.' As in the Soviet Union, Lysenko's rejection of Mendelian genetics and T. H. Morgan's chromosome theory became dominant in China in the 1950s and 1960s for ideological reasons. This trend was only reversed after the accession of Deng Xiaoping to power in 1978. Medical experts and population specialists were put into powerful positions as official policies aimed at the limitation of births were initiated by the government from the early 1980s onward. Besides the one-child family program, by which the government only in exceptional circumstances allows parents to have more than one or occasionally two children, an important component of these policies has been the improvement of the quality of newborn babies.

The one-child family policy has effectively prepared the terrain for a better acceptance of eugenic legislation among large sectors of the urban population: many families that are allowed to have one child only are keen to avoid 'defective' births themselves and also tend to favor boys. A prolific medical discourse has responded to some people's concern for healthy offspring, a virtuous child, or even a genetically improved line of descent. Numerous pamphlets of scientific vulgarization thus dispense advice on the art of engendering a prodigy child, suggesting that the eugenist vision of the government is shared to a great extent by a population that is anxious to avoid what are called 'inferior births.'

As the result of such consensus, local regulations have been passed virtually unopposed in a number of provinces and cities since the late 1980s. On 25 November 1988, the Standing Committee of the National People's Congress of Gansu Province passed the country's first law prohibiting 'mentally retarded people' from having children. According to the law, those whose condition was either inherited or a consequence of marriage between close relatives were not allowed to have children; none were allowed to get married unless they had undergone sterilization surgery; those who had married before the promulgation of the law were also to undergo sterilization surgery; and pregnant women suffering from mental retardation were required to have their pregnancies terminated. Individuals who violated the law by allowing 'mentally retarded people' to have children would be punished by both administrative and economic means. Liaoning Province enacted a similar law in February 1990, while Zhejiang Province passed a law on the preservation of 'eugenic health' in June 1992 to combat the increasing incidence of 'cretins,' who were estimated to number more than 300 000. The Henan eugenics law of 1992 requires that if one partner in a married couple suffers from a 'chronic mental disorder' such as schizophrenia or manic depression, that partner shall be sterilized. The implementation of such sterilization laws at the provincial level is advanced by a system of incentives and disincentives. People who refuse to be sterilized or anyone who impedes the sterilization of another may be subject to penalties. For example, Henan's eugenics law

requires prompt reporting of those diagnosed as 'needing to be sterilized' who refuse to accept the operation. Differential fines for noncompliance with 'eugenic measures' are imposed for rural and urban residents.

Under pressure from a variety of lobbies, mainly family planning experts and geneticists, the provincial laws finally culminated in the People's Republic of China passing eugenic legislation at the national level at the beginning of 1995. The law aims to prevent 'inferior births' from becoming a burden on the state and society. Renamed the Maternal and Infant Health Law after protests against a preliminary draft was entitled Eugenics Law (*Youshengfa*), it supports the systematic 'implementation of premarital medical check-ups' in order to detect whether one partner in a couple suffers from a 'serious hereditary,' venereal, or reproductive disorder, a 'relevant mental disorder', or a 'legal contagious disease': it asserts that those 'deemed unsuitable for reproduction' should be urged to undergo sterilization or abortion, or to remain celibate, in order to prevent 'inferior births.' During pregnancy, medical testing will be compulsory and can be followed by termination if the fetus is found to have a serious disorder. The requirement to undergo a premarital health check was abolished in 2003, although in some provinces doctors continue to have the power to prevent people judged to be 'unfit' from marrying.

In the absence of any detailed studies by social scientists and population experts, concrete information on the implementation of eugenic laws is still missing. Foreign observers, however, have emphasize that the implementation of eugenic legislation not only undermines the rights of the person vis-à-vis the state, but it is based on controversial, if not antiquated, theories of human heredity (O'Brien, 1996; Lancet, 1995; Nature, 1994).

Japan

In Japan, eugenics developed gradually after modernizing intellectuals encountered evolutionary theories in the works of Charles Darwin and Herbert Spencer in the 1880s. In the wake of the Meiji Revolution (1868), science and technology were perceived to be the key to national defense in an era of intense imperialism. As in many other countries, racial improvement became a popular notion among leading intellectuals who viewed the world in terms of a 'struggle for existence' among competing 'races.' Belief that individual reproductive decisions should be controlled by the state in the name of collective health flourished during the first half of the twentieth century. In the 1910s, works on eugenics by Umino Kōtoku, Nagai Hisomu, and Saitō Shigesaburō appeared, closely related to an increased interest in birth control, sex education, and public health.

Specialized journals were also established in the 1920s, both the *Yūzenikkusu* (Eugenics) and the *Yūsei Undō* (Eugenics Movement) being crucial in spreading eugenic discourse to a wider audience. As in China, belief in the power of heredity led many followers of the eugenics movement to view venereal disease, tuberculosis, leprosy, and alcoholism as heritable conditions that should be strictly administered by the state in order to prevent the increase of 'inferior offspring.' Eugenics became part of such widely discussed themes as evolution, degeneration, civilization, and modernity, and touched on a wide variety of emerging fields such as maternity, psychiatry, criminology, public health, and sex education (Sumiko and Bartholomew, 1998; Suzuki, 1975).

In Japan, too, the orthodox Mendelian roots of eugenics were often disregarded in favor of a more flexible approach to eugenics that emphasized belief in the transmission of acquired characteristics. Contrary to China, however, eugenic ideas provided a rationale for welfare policies with deep institutional and legal ramifications. A first attempt to implement eugenic legislation took the form of an appeal to the Imperial Diet in the early 1920s (Matsubara, 1998). Proposed by the New Women's Federation, the petition sought to legally restrict the marriage of individuals with venereal diseases as a means of strengthening the nation. Despite support from leading intellectuals as well as members of the Imperial Diet, the petition was not adopted. Only in 1934–35 was a Racial Eugenics Protection Bill introduced by the Imperial Diet, which proposed the sterilization of persons with mental and physical diseases deemed to be hereditary, including serious criminals who were claimed to transmit their 'bad traits' to their descendants. The Japanese Association of Racial Hygiene, on the other hand, campaigned for a eugenics law limiting sterilization to patients with hereditary diseases. Headed by Nagai Hisomu, the group drafted a sterilization bill in 1936 based on the German Sterilization Law of 1933. Only in 1940, however, was a National Eugenic Bill passed, its enactment leading to heated controversy among government representatives and members of the medical professions. Objections came both from nationalists defending the need of the state to increase its population and from geneticists questioning the scientific validity of eugenics. While the bill came into effect a year later, the government was compelled to prevent the enforcement of eugenic sterilization: by the end of the Second World War, only 454 operations were performed under the eugenics law.

After Japan's defeat in the Second World War, questions of 'racial survival' surfaced again in the context of occupation by the Allied Powers (Matsubara, 1998). As abortion was legalized, a broad consensus emerged within medical and political circles around the need to prevent not only 'inferior descendants,' but also the reproduction of patients deemed to have 'infectious diseases' such as leprosy and nonhereditary mental disorders in the name of 'eugenic protection.' Supported by conservative advocates as well as socialist politicians, the Eugenics Protection Law (*Yūsei hogohō*) of 1948 gave legitimacy to eugenic sterilization without the consent of the patients considered. The law remained the foundation for eugenic sterilizations throughout the second half of the twentieth century: involuntary operations reached over 16 500 cases by 1996, while a further 1500 leprosy sufferers segregated in sanatoriums had been sterilized with consent by 1992. In 1996, the law was finally revised and renamed the Maternal Protection Law, while the eugenic clauses on sterilization and abortion were deleted. Even after these legal changes, however, the government refused to critically examine the practice of compulsory sterilization on eugenic grounds, despite severe criticisms from a variety of civil rights groups (Norgren, 1998).

Conclusion

The legacy of eugenics is still highly visible today in many countries, including less researched parts of the world outside 'the West.' As the examples of China and Japan demonstrate, eugenic ideas elaborated during the first half of the twentieth century continue to carry scientific and legal credibility. While crude eugenic programs sponsored by the state may have become less frequent today, eugenic ideas are prominent in contemporary debates about new medical techniques for isolating and manipulating genes. During the heyday of eugenics, assumptions about 'race,' gender, and class pervaded genetic research: with the revolution in human genetics since the end of the twentieth century, social and political factors continue to exert formidable influences on scientific research. Eugenic laws have been passed at the provincial and national levels in China, a country that has curbed the reproductive freedoms and civil rights of individuals on behalf of the 'public good.' Even in democratic countries like Japan, however, marginalized people may be treated in a discriminatory way, as social prejudice and economic interest influence the genetic information made available to families, employers, hospitals, insurance companies, or welfare systems. As much as 'ethnicity' is a concept that is sometimes used as a thinly disguised substitute for the outdated notion of 'race,' discredited eugenic ideas have thrived on rather than suffered from the revolution in human genetics in some parts of the world: East Asia is no exception.

Eugenics in Europe

Abstract

This article surveys the history of eugenics in Europe, noting its origins in the growing comprehension of the power of science to understand the human body and in the increasing ambitions of the state and the social and scientific elites to exert control over the social body. The article then surveys major events and personalities of the eugenics movement in various European countries over the course of the nineteenth and twentieth centuries, placing the movement firmly in its political, social, and cultural contexts.

Although eugenics was not exclusive to Europe, it is there that it originated and found some of its most fully-elaborated theories and practices. Precursors to this so-called science of improving human populations through genetics and theories of heredity had existed in the West since antiquity, with Plato's advocacy of judicious breeding of the citizens of his ideal *Republic* constituting one of the earliest and most famous examples. What might be called a proto-eugenic discourse emerged during the seventeenth and eighteenth centuries, as ideas on human perfectibility, theories of generation and inheritance, and considerations of demography and national strength all became growing concerns with intellectuals, scientists, and the ruling elites. The nineteenth century saw accelerating attention to these matters, as the simultaneous development of powerful new scientific discourses and emergent centralized and bureaucratized nation-states gave powerful impetus to ambitions and attempts to manipulate human health for the supposed betterment of large populations. The eugenics movement, both in its intellectual and scientific forms and its manifestations in state policies, reached its apogee in the first half of the twentieth century. The frenzy of racial utopian thinking that marked the Second World War and the Holocaust seriously undermined faith in eugenics, as did other postwar developments in science and politics. By the end of the twentieth century, eugenics was so thoroughly discredited that its name disappeared from acceptable mainstream discourse. Yet its legacies have not disappeared and continued advances in the ability to manipulate human life at the genetic level mean that the problems raised by eugenics are far from vanishing for good.

An Englishman, Francis Galton, a cousin of Charles Darwin, coined the term eugenics in his 1883 book *Inquiries into Human Faculty and Its Development*, deriving it from the Greek word *eugenes*, literally meaning 'well-born.' Galton, who had been interested in questions of heredity since his work *Hereditary Genius: An Inquiry into Its Laws and Consequences* of 1869, described eugenics as meaning "good in stock, hereditarily endowed with noble qualities." He and those who came after him described eugenics as a science, relying on the latest insights into the development of life provided by Darwin's revolutionary theory of evolution and an increasing understanding of genetics. The perceived social benefits of the science of eugenics, that of applying ideas of heredity in practice to improve the health of the social body, provided eugenicists with a wide audience and in some cases official government support. But this very practicability subjected eugenics to even more effective social and cultural pressures than is usually the case in the formation of bodies of scientific knowledge (even if social and cultural forces are never absent from the development of science). Steven Jay Gould has pointed out that certain disciplines are particularly subject to external social pressures because they have a low ratio of data to social impact – they tell more about social change than anything else, and they formulate their original questions "in such a restricted way that any legitimate answer can only validate a social preference" (Gould, 1996: pp. 54–55). The social preference of eugenicists was always very clear: the prevalence of certain elements of society or sections of the population over others, whether defined by racial, ethnic, or class superiority. Some individuals and groups were more 'fit' than others and deserved to propagate their kind, while other 'less fit' individuals and groups should face restrictions or prohibitions on their procreative activities. In extreme cases, eugenicists contested and even sought to prevent the continued existence of the 'less fit.'

Cultural and political factors and social preferences decisively influenced the format of eugenic research and activity in a variety of national contexts. Different social concerns over matters of race and class differentiated these separate national eugenics movements, even as some commonalities and international scientific networks linked them in guiding research imperatives and focusing eugenic policy. The desire to bring growing expertise to bear on public policy also played a role, because medicine was becoming increasingly professionalized over the late-nineteenth and early twentieth centuries. It is no accident that leading eugenicists were most often crusading medical men, not laboratory geneticists. In short, eugenics is a prime example of what Tzvetan Todorov calls "scientism … the use of science to establish an ideology" (Todorov, 1993: p. 114), through the increase of the persuasive power of medico-scientific discourse on social problems during this period. The idiosyncratic science of eugenics provides an explicit example of how closely the scientific endeavor is intertwined with immediate social, political, and cultural imperatives. Eugenics was an important force in nearly all industrialized societies and certainly in all of Europe by the early twentieth century. In each case, the particular needs and

desires of the prevailing national political and social regime seeking to classify, control, maximize, and marshal its population and human capital, determined its eugenic policies to a large extent.

Origins

The Scientific Revolution of the seventeenth century had profound effects not only upon the European intellectual climate but also on Western political development. By the eighteenth and nineteenth centuries, scientific knowledge was increasing in volume, scope, and sophistication at a remarkable rate. Many new fields of inquiry rapidly developed and institutionalization and professionalization soon followed with dramatic growth. At the same time, scientists were busy forging links with the emerging centralized and bureaucratic states of Europe. Those in power soon realized that a partnership between science and politics could offer a mutually beneficient relationship, and politicians and legislators began to lean heavily upon scientific experts, methods, and data in formulating social policies. Effective social policy was certainly an urgent priority in this age of industrialization and centralization. Modernity brought with it deep tensions that constantly threatened the tenuous hold that the new bureaucracies maintained upon both the peoples over whom they ruled and the seemingly impersonal accelerating forces of history. The new sciences appeared to offer a coherent method for resolving these tensions within the social order.

The French thinker and historian Michel Foucault designated "what brought life and its mechanisms into the realm of explicit calculations and made knowledge-power an agent of transformation of human life" as "biopower"(Foucault, 1990: p. 143). This marked the emergence, simultaneous with the advent of modernity, of myriad new technologies designed to exert control over and channel the energies of individual bodies in the ostensible interests of the larger social body. The state, or groups representing the interests of the state, wielded "a certain mode of detailed political investment of the body," and a ubiquitous "new microphysics of power," acting as disciplinary authorities, closely monitoring people's health and movements (Foucault, 1977: p. 139). This attention to individual bodies was predicated on a view of the body as a machine, which could be manipulated and fine-tuned to maximize its utility and output. The goal of these controlling apparatuses in focusing on particular human beings was to maximize the utility of populations as a whole. This "biopolitics of the population" sought to promote the health and well being of society, which is more than just the sum of its parts. Society itself, in this line of reasoning, is analogous to a living organism. It is subject to diseases and cures and could be healthy or ill, strong or weak, normal, or pathological.

New technologies of power made the extension of biopower possible during the nineteenth and twentieth centuries. The ruling elites and the states they served, both from within and outside formal political bodies (professionals such as scientists and doctors, scientific societies, expert advisors, and technocrats) were above all concerned to divide the populations in which they lived and over whom they had control into 'normal' and 'pathological,' or at least to place individual bodies in a hierarchy of value. These were conscious and unconscious strategies of power, to be sure, but they were also responses to the political, economic, and class tensions called into being by modernity. In this sense, eugenics became a perfect example of both the powers and the anxieties unleashed by modernity. Not only did the emergence of mass culture, industrialization, and the many other novel problems and conditions of modern life generate new concerns about the social body, but these same conditions made imperative the development of new methods for controlling and organizing individual bodies. Political and social authorities began to concern themselves with the examination, classification, diagnosis, organization, and treatment of people, both as single, distinct entities and as aggregate populations.

The connection between individual bodies and the aggregate population which they constituted was never quite so important as it became during the rapid economic and demographic expansion of the late eighteenth century. In 1798, Thomas Malthus published his thoughts on the relationship between the two in his *An Essay on the Principle of Population*. In it, he postulated that human beings' biological reproductive drives were inexorably propelling them to multiply beyond the limits of their available sustenance and that rapid technological advances only postponed the inevitable overpopulation of the planet. Malthus reversed the conventional wisdom of the time concerning healthy bodies. According to his argument, healthy individual bodies did not contribute to the overall well-being of society. Rather, virile and well-fed people reproduced at a dangerously higher rate. This thinking was in line with an elite Victorian tradition of suspicion and fear of the awesome and seemingly autonomous power of certain segments of the population. By the middle of the nineteenth century, educated and upper class Europeans would come to see the unchecked proliferation of members of the laboring class as a threat to (their) civilization.

Yet inter-racial worries laid the groundwork for these intra-racial concerns and decisively shaped eugenic anxieties and discourse. Scientific language and methods already informed nineteenth-century thinking about race when Charles Darwin's *On the Origin of Species* appeared in 1859 and provided racial theorists with a new and powerful way to conceptualize racial divisions. Writers such as Arthur de Gobineau had always been adamant about placing the various human races in a qualitative hierarchy with the white race at the top. He justified fears of miscegenation with empirical data demonstrating the inferiority of both nonwhites and persons of mixed race. But now racial theorists combined Darwin's theories of evolution and natural selection with their observations about the relative levels of 'civilization' achieved by the various races, maintaining that whites represented the most advanced stage of human evolution. They cited the technological and artistic achievements and near worldwide hegemony of Europe as conclusive proof of white superiority and even argued that the white race constituted a different, more highly developed species of human being. This flew in the face of Darwin's skepticism about truly 'specific' differences among different groups of human beings. In his 1871 *The Descent of Man*, Darwin cited cross-fertility and the 'fusion' of humans of different races who lived in close proximity and who chose to intermingle and

breed across racial lines, as conclusive evidence that the various races among humans did not constitute different species. Still, racialist thinkers ignored Darwin's conclusions on race while retaining his evolutionary theories in order to invest their opinions with the impressive mantle of the new science.

So underlying eugenics was a peculiarly scientific form of social Darwinism. Eugenicists advocated methods and policies based on Herbert Spencer's "survival of the fittest," and rather than natural selection, eugenicists sought to promote the concept that artificial selection would safeguard and improve the health of the social body. They justified these artificial interventions into the process of evolution by citing the artificially dysgenic conditions of modern civilization. Galton himself vaunted these interventions as "more merciful and not less effective" than natural selection, which relied upon "excessive production and wholesale destruction," while eugenics sought to bring "no more individuals into the world than can be properly cared for and those only of the best stock." But why was the need for eugenics so increasingly urgent during precisely this period in European history? Ultimately, eugenicists transmuted concerns over racial competition and interracial contamination into fears of intra-race decay, known by the French term *dégénérescence*, or degeneration. Darwin's theory of evolution, combined with ideas about human heredity, led many to believe that a 'devolution' of the human species was possible. Writers like Max Nordau fulminated against the corruption of modern culture that they saw around them and determined that the origin of this degeneration must be found in human heritability. Nordau built upon the work that originally introduced the term, B.A. Morel's 1857 *Traité des dégénérescences*, and defined the condition as "a morbid deviation from an original type," which was transmissible and would spread more widely and increase in intensity with the propagation of the original carrier's descendants. The conditions of modern life, centered in the frenetic, unhygienic environments of ever larger cities promoted this decay, which then developed further in the unhealthful altered circumstances of natural heredity. Nordau's special contribution, aside from popularizing the notion in his international best-selling *Degeneration* of 1892, was to diagnose the condition in the new medico-scientific discourse that resonated so loudly in *fin-de-siècle* Europe. With such a powerful and compelling analytical tool, he and others were able to attribute biological causes to perceived social ills.

Although Nordau found degeneration everywhere, even in the ranks of the artistic and literary elite, discourse about degeneration came to focus primarily on the unfortunate poor and the demonstrably 'feeble-minded,' mentally and emotionally disabled persons. The intensifying pressures of modernity in Europe over the nineteenth century led to political struggles that thrust 'the masses' decisively into the political arena. Spectacular examples during the upheavals of 1848 and the 1870 Paris Commune frightened the newly empowered bourgeoisie and provoked intellectuals to view the large pool of wage-laboring poor as a biological as well as a political threat. Thus, the social and political elites could characterize social problems in the comfortingly objective terms of science. A medical diagnosis of inherent and heritable degeneracy conveniently and compellingly explained the impersonal and inscrutable forces of history. Concerns about degeneration proliferated, and penetrated into works of popular literature, the social sciences, and political debates, as well as the medical and biological sciences.

Discourses about degeneration, a social anxiety articulated as a medico-biological concept, predictably took on different characteristics in different national contexts. In Great Britain, the term resonated distinctly with class tensions. For example, psychiatrist Henry Maudsley focused on the rampant mental deficiency among the working poor in urban industrial centers. The squalor and inbreeding of the slums in which they lived, he argued, rendered the poor pathologically degenerate, and the unchecked twin processes of degeneracy and procreation threatened to engulf British society. The widely publicized poor condition of recruits from the working class serving in the Boer War (1899–1902) convinced many of the urgency of stopping the apparent decline of the nation's biological stock. In France, the birthplace of the theory of *dégénérescence*, concerns mixed with anxieties over the nation's declining birthrate, especially in comparison with a more fecund and recently united Germany (the process of German unity itself crystalizing in the humiliation of France in the 1870 Franco-Prussian War). Fear of population decline put the focus on specific socio-medical problems, such as tuberculosis, alcoholism, and pre- and post-natal health, the amelioration of which could stem the decline and even regenerate the nation. In Italy, the most salient evidence of degeneration seemed to be intractable criminality. Unrest and crime in this recently and uneasily unified nation-state led legendary criminologist Cesare Lombroso to search for ways to identify hereditary criminals by their physical and mental characteristics. He and men like Enrico Ferri recommended the segregation of 'criminal types,' preventing their reproduction, thus checking the effects and spread of biological-social decline. In the Scandinavian countries of Demark, Norway, and Sweden, rapid modernization and its attendant problems, declining birthrates, and emigration seemed to suggest an anthropological approach to degeneration, in this region where the discipline was particularly well developed. Racial hygiene movements organized to address the issue, and Denmark's 'Anthropological Committee' eventually became the leading advocate in that country for eugenic solutions to the problem of degeneration.

Degeneration was the problem for which eugenics was the solution – the rationale was that the medical problem of degeneration called for a medical cure. Eugenicists, often doctors or men with a background in medicine or public hygiene, identified degeneration as the root of all modern social and political problems. Eugenics offered a utopian way out of the dead end into which modernity seemed to be driving human civilization and its highest expression in Europe's advanced industrialized societies. Ironically, and perhaps ingeniously, modernity could cure itself, since eugenics represented to its adherents the most modern, cutting edge science of the day, built upon the solid foundations of Darwinian biology and pioneering work in the understanding of human genetics. The problems of modernity, once attributed to biology and inheritance, could be made subject to scientific study and treatment. But it was clear to many eugenicists that it was going to be necessary to enlist the coercive power of the state in order to enact specific eugenic measures.

Eugenics in Formation, 1904–33

If the origins of eugenic thinking lie far back in the Western tradition (in dreams of perfecting individual human bodies by intervening in the procreative process, thereby perfecting the social body as a whole) and if the nineteenth century saw the crystallization of the component elements of eugenic thinking (social Darwinism, racism, and theories of degeneration) through scientific advances in understanding human biology, then the early twentieth century was an era of institutionalization and the articulation of eugenics as a body of both thought and social policy. Galton, writing in 1908 about the science and movement he had founded, succinctly described the twin imperatives of eugenics: firstly, "to check the birth-rate of the Unfit, instead of allowing them to come into being, though doomed in large numbers to perish prematurely"; secondly, to improve "the race by furthering the productivity of the Fit by early marriages and healthful rearing of their children." These two forms became known as 'negative' and 'positive' eugenics and they combined in different ways in different national contexts, depending upon the social and cultural forces driving interest in eugenics and the policies that flowed from them. In some places negative eugenics held sway, while in others positive eugenics prevailed. In others still, the two coincided, overlapped, or even mixed. Eugenic thinking was never uncontested, to be sure, but in virtually all European societies during this period the idea prevailed that social and civilizational health was largely reducible to heredity, and that humans could intervene effectively in the hereditary process by controlling the reproductive behavior of certain elements of society.

Positive eugenics, the less well-known and seemingly more benign of the two, involved the encouragement of healthy, eugenically sound marriages, the improvement of pre- and post-natal care, campaigns against diseases such as alcoholism and tuberculosis, and a host of other programs. Proponents designed these measures to maintain the health of the fit, so that they would reproduce healthy and numerous offspring, and to improve the health of the less fit members of society, who would then pass on to their descendants their improved condition (or at least would not pass on degenerative diseases). Negative eugenics, on the other hand, involved the prohibition of dysgenic unions, where one or both of the partners was allegedly biologically unfit. Attempts to prevent undesirables from propagating their kind usually took one or more of four separate forms: marriage restrictions, immigration restrictions, sexual segregation, and sterilization. Clearly, the state would be required to play a preponderant role in implementing these policies since they all required coercive authority, legal regimes, broad control over large segments of society, and restrictions on individual freedom.

The state would have to provide the legal and most of the administrative infrastructure for the execution of eugenic policies. Nonetheless, the status of eugenics as a broad-based social and scientific movement meant that individuals and interest groups outside the state would play a very large role in originating and elaborating eugenic policies at the level of ideas, pressuring for their implementation via government action, and staffing the bureaucracies that carried them out. Social reformers of all stripes advocated for eugenic policies, but the real impetus for the movement came from medical biologists, physicians, and academics in the social sciences. This mix of advocates, along with the generalized social anxieties of the bourgeois elites faced with an accelerating modernity, gave eugenics its distinctive quality of being at once a social movement and a science. The ways that social and cultural imperatives decisively influenced the direction of the science of eugenics and eugenic policies is clear from the different forms that they took in the various countries of Europe during the first half of the twentieth century.

Although rooted in the nineteenth century, eugenics as a movement began and rapidly spread at the very beginning of the twentieth century. Books, concepts, organizations, and even legislation laying the foundations for the movement appeared earlier, but the year 1904 saw the constitution in London of the Eugenics Record Office, the first institution to deploy the term by name and take the science explicitly as its guiding principle. The United States would emerge nearly simultaneously as one of the most important sites of eugenic thinking and policy, with its own Eugenics Record Office, at Cold Spring Harbor in New York, opening in 1910 (the British institution had changed its name in 1907 to the Francis Galton Laboratory for the Study of National Eugenics). Over the following decades, eugenics would also develop as an important force in societies across Asia, Latin America, and beyond, but the movement originated and was anchored earliest and most firmly in Europe.

Great Britain, of course, as the home of both Darwin and Galton and the site of the original Eugenics Record Office, blazed the path that other nations would follow, though each would eventually pursue a eugenics that best suited their social, cultural, and political circumstances. In the United States the eugenics movement under the influence of men like Charles Davenport displayed a strong Mendelian bent and a concern with genetics, and under the influence of the nation's distinctive history and culture, displayed a clear preoccupation with race and immigration. Eugenicists in Britain viewed class divisions as the most pressing problem to which eugenics might offer a solution. British science not only resisted Mendelianism, but because the British class system was notoriously rigid, the problem of degeneration appeared in this context as a diseased urban blight brought on by rapid industrialization and the need for cheap labor, spreading out into the 'healthy' population. Race and ethnic diversity, at this stage of British history and outside of Ireland, did not raise critical problems domestically. British eugenicists, in short, worked in the tradition of Galton, who stressed the heredity of both physical and social characteristics and warned of the consequences of a more fertile but less intelligent underclass. Class anxiety about degeneration and solutions by means of eugenics later manifested themselves as warnings about internal, class-based social and hereditary decay, in the writings and pronouncements of writers like H.G. Wells and Havelock Ellis.

But men of science were influential in the British eugenics movement. Karl Pearson was the most famous, a mathematician and biometrician who taught statistics at University College London, a protégé of Galton and head of the Galton Eugenics Laboratory for almost three decades. He also held the first Galton Chair of Eugenics at University College London, which Galton had endowed upon his death in 1911. Britain was an international center of eugenics research and activity,

seeing the foundation of the Eugenics Education Society in 1907 (becoming simply the Eugenics Society in 1926), with Galton as honorary president. From 1911 to 1928, Charles Darwin's son, Major Leonard Darwin served as the Society's President. The First International Congress of Eugenics in London in 1912 paid tribute to Britain's importance to the international movement. Pearson, who was not a member of the Eugenics Society, founded the important international journal, *Annals of Eugenics*, in 1926.

Still, despite all of this intellectual activity, enacting eugenic policies proved difficult in Britain, much more so than in the United States. An 1895 Connecticut law prohibited marriages of epileptics, imbeciles, and the feebleminded, while Indiana's 1907 Compulsory Sterilization Law pioneered legal sterilization, targeting confirmed criminals, idiots, imbeciles, and rapists. The two laws together established the United States as the most fertile ground, along with Germany eventually, for extreme negative eugenics measures. In Great Britain, in contrast, even lawmakers sympathetic to eugenic ideas found restrictive measures unpalatable, and politicians on the side of labor were concerned with the effect of negative measures on the working poor. Thinkers of a socialist bent, such as George Bernard Shaw, still accepted the widespread discourse on eugenics, but advocated more positive means. In Shaw's case, this involved removing rigid class distinctions and the social restrictions they imposed to allow for better, more eugenic pairings.

France saw an important eugenics movement arise during this very same period, but eugenics took a very particular form in that country. Even more than in Britain, French scientists, thinkers, and legislators resisted negative measures and, in fact, provided one of the most congenial homes in the world to positive eugenics. The particular social and political problems that characterized French discourse about degeneration – fear of a declining birthrate and international marginalization – along with patriotic sentiment, led French eugenicists to subscribe to the theories on heredity propounded by their countryman Jean-Baptiste Lamarck, rather than those of the Englishman Darwin. Lamarckian biology led them to believe that physical changes wrought by the environment on an individual organism during its lifetime were heritable by its offspring. This meant that positive eugenic measures implemented to improve the health of individual members of society would improve the biological capital from which future generations would draw. In a strictly Galtonian or Mendelian view of heredity, however, positive measures could improve the health of the already fit and encourage them to produce more numerous fit offspring, but the unfit carried, fatally and permanently, the seeds of future decay and had to be stopped with negative measures from procreating. The French eugenic movement's positive approach aligned it with the pronatalist and social hygiene movements. Even advances in understanding genetics – Mendelianism and Weismann's theory of the continuity of the 'germ plasm' – failed to alter the approach of most French eugenicists. The movement, highly influenced by the social and political imperatives to maintain and increase the quantity of the population, rejected negative measures that would prevent procreation. It sought instead to improve the quality of the population, which according to Lamarckian principles would, in turn, increase the quantity.

Physician Adolphe Pinard, a leading and typical figure in French eugenics, built his career and fame on public advocacy of pre- and post-natal health. This science of healthy babies, known as *puériculture*, stressed the importance of parental health not just during pregnancy, but even at the moment of conception. Parents, after all, were in a position to pass on their acquired and maintained health to their children. Enthusiasm brought back by the French delegation to the First International Eugenics Congress in London in 1912 led to the founding of the French Eugenics Society at the end of that year. Pinard was a founding member and vice president, and the organization published a monthly journal, *Eugénique*. Physicians constituted more than half the group's founding members. The Society's agenda included government action to manage sexual activity, marriage, birth and life expectancies via *puériculture*, social hygiene, and eugenics.

Suspension of activities during World War I slowed the group's momentum and caused it to lose membership. The 1924 creation of the National Office of Social Hygiene incorporated a part of the Society's agenda and in 1926 *Eugénique* ceased publication. Yet the Great War's appalling demographic impact inspired French eugenicists to reemphasize social hygiene and positive eugenics in order to rejuvenate a French population facing greater and more specific threats than a vague, generalized 'degeneration.' Now, more than ever, the production of more and healthier children was critically urgent and if the Society was organizationally weak, other institutions and actors were now more open to eugenic ideas. Public discussions of eugenics proceeded, even if they did not rejuvenate the Society. In 1926 Pinard, now a member of the Chamber of Deputies, proposed legislation to require all French males to submit to a premarital medical examination. But years of debate held up the bill's progress. It would not be until later in the 1930s and during World War II under the Vichy regime that interest in eugenics (even negative eugenic proposals unthinkable in earlier periods dominated by fears of depopulation) had concrete results.

Eugenic discourse in Germany differed significantly from that of its French neighbor. Germans did not fear a declining birthrate since their nation enjoyed a demographic boom in the late nineteenth and early twentieth centuries. Thus, German eugenicists, instead of molding their scientific views around cultural fears over numerical population decline, were subject to social Darwinist and racist cultural anxieties, talking freely about the survival of the fittest and about restricting the reproduction of certain members of society. Nowhere is the impact of cultural imperatives, on eugenics as well as on scientific discourse in general, more clear than in the contrast between the French and German 'styles' of eugenics.

Despite this contrast, both movements concerned themselves deeply with what they both called hygiene. But while eugenics in France and elsewhere often had close links with social hygiene movements, the German eugenics movement was rooted in *Rassenhygiene*, or racial hygiene, betraying an underlying concern with safeguarding both racial health and purity. Alfred Ploetz, who coined the term, evinced a keen interest in manipulating heredity to improve the health of the German population, or 'race.' In 1904 he founded the eugenicist journal *Archiv für Rassen- und Gesellschaftsbiologie*, and in the following year, the Society for Racial Hygiene

(*Gesellschaft für Rassenhygiene*). Although some German eugenicists were skeptical of restrictive, negative measures, worrying like their French counterparts over the size of their population as well as its quality, there was still a marked tendency, heightened by the intense attention to race, to think in terms of preventing the propagation of the unfit while promoting the fecundity of the fit. Also strongly present in German eugenics was a technocratic and managerial logic, best exemplified by physician Wilhelm Schallmayer, who strove to improve national efficiency through racial hygiene. Although he rejected the ardent racism of many other German eugenicists, he advocated a rational management of population via cost-benefit analyses to determine the future social cost of dysgenic reproduction, along with government action to prevent or reduce this dysgenic behavior.

But the logic of extending state power to increase 'national efficiency,' through the rational management of the population as a resource, involved dividing individuals into categories of valuable and less valuable, or valueless. Once the Nazis later created an environment where racial criteria almost exclusively guided these determinations, the logic of German eugenics played out to its murderous end. What Foucault called the "biopolitics of the population," the regulation of individual bodies through medico-scientific discourses in the supposed interests of the larger social body, was evident in German eugenics from an early stage, long before the Nazis made the approach notorious. German eugenicists, even those eschewing racism like Schallmayer, saw it as their duty, and the state's duty, to watch over and supervise, to maintain and regulate the biology and reproductive behavior of each individual as part of the species, or at minimum of the larger national community.

The three Great Powers of Britain, France, and Germany were certainly not the only homes of eugenic activity in the early twentieth century. Russia, Austria-Hungary, and Italy, themselves sometimes also ranked as Great Powers, all hosted important eugenics movements. Eugenics in Russia before the Bolshevik Revolution of 1917 rejected the emphasis on class and race found in other national movements, emphasizing the role of the environment in shaping heredity, much as in France. Geneticists such as Konstantinovich Kol'tsov and Yuri Alexandrovich Filipchenko were the key figures in the movement by the 1920s, and a move toward Mendelianism and a 'socialist' eugenics characterized their efforts. But Lamarckianism was more in line with official Soviet ideology, negative measures never found wide acceptance, and social hygiene was of continuing importance to the movement. Eugenics in the Austro-Hungarian empire before its dissolution in 1918 was closely aligned with the German *Rassenhygiene* movement in a 'Greater German' approach to questions of race and heredity, while public health policies in the Austro-Hungarian empire indicated that leaders in Vienna sought to enhance imperial control and interests via intervention in the health of individuals and the larger social body. In Italy, although Lombroso's ideas about hereditary criminality were internationally influential, the movement as a whole hewed to an environmental view that rejected negative eugenics. Moreover, a strong Catholic tradition, which showed itself hostile to eugenics in many countries, precluded strict biological determinism. Italian biology as a whole tended not to stress racial purity and to accept variation and diversity as healthy.

Switzerland and the Scandinavian nations were also active sites of eugenic activity. Under the influence of eugenicists, the Swiss canton of Vaud, in 1928, became the first European polity to enact a compulsory sterilization law aimed at the mentally ill. One of the earliest European societies devoted to discussing and promoting eugenic ideas was Denmark's *Den Antropologiske Komité* (Anthropological Committee), founded in 1904, which later became a private eugenics society. All three Scandinavian countries of Denmark, Sweden, and Norway, as well as the Nordic states of Finland and Iceland and the Baltic states of Latvia and Estonia, introduced eugenics-inspired sterilization laws. Almost all of these, however, came into force during the 1930s. If the period from a decade before the First World War through the late 1920s saw the flourishing of eugenic thinking and activity in scientific journals, research programs, and societies, it was the following decade, (which also saw the rise to power in Germany of Adolf Hitler) and the years of the Second World War that constituted the height of eugenic policymaking and enforcement by European states.

Eugenics in Power, 1933–45

The story of eugenics in power during the 1930s and 1940s is more quickly told than that of the movement during the period of its formation. This is not because eugenics activity tapered off – on the contrary it grew in intensity and concrete effects – but because the story is, in many cases, a straightforward one of policymaking and state action. This is most obviously true in the case of Germany, under the explicitly racist and eugenicist Nazi regime from 1933. But the repeated crises of the 1930s and the outbreak of war in 1939 stoked desires and opened up opportunities in many countries to act to achieve eugenicist ends, whether it was manifested as an urge to protect populations from the alleged perils of hereditary decay or as an impulse to realize utopian visions of racial and ethnic purity and human perfection.

Germany is the most important and notorious case, and if an account of the origins and early stages of eugenics must begin with Great Britain, the story in the 1930s and 1940s must start with Hitler's ascent to power in 1933. The first and most general effect of the Nazi regime on German eugenics was to weld together the concern of some eugenicists with welfare measures designed to improve public and health and hygiene in the interest of the future of the population, and the obsession of the Nazis and not a small number of eugenicists with race. Only a few months after coming to power, Hitler promulgated a sterilization law aimed at those with supposedly hereditary diseases such as feeblemindedness and other mental or physical impairments. The eugenicist logic underlying the measure was clear from its name, Law for the Prevention of Hereditarily Diseased Offspring (*Gesetz zur Verhütung erbkranken Nachwuchses*), and eugenicists indeed took a central role in its framing. Ernst Rüdin was a key figure, as he had been in the movement since he helped Ploetz found the Society for Race Hygiene in 1905. Eventually, some 375 000 people were legally sterilized, virtually all without their consent and some without even knowing they had undergone the procedure. The eugenic logic of sterilization

combined with one of the Nazis' most ardent racial obsessions in 1937, when 385 children born of German mothers and French colonial soldiers during the post-WWI occupation of the Rhineland were sterilized.

Nazi measures to segregate racially undesirable people from the ethnically pure German population, in order to prevent the pollution of the gene pool through uncontrolled reproduction, displayed the same blend of eugenic logic and strategies combined with Nazi racial logic. The 1935 Nuremburg Laws that forbade sexual relations between Germans and non-Germans (Jews, primarily, but also other so-called racial inferiors) took inspiration from the work on interracial mixing by Eugen Fischer, who in 1927 had become the first head of the Kaiser Wilhelm Institute for Anthropology, Human Heredity, and Eugenics in Berlin. Rector of the University of Berlin from 1933, Fischer remained closely tied to the Nazis and their racial policies, and in 1935 upon promulgation of the Nuremberg Laws, he publicly praised them and thanked Hitler for having presented to eugenicists such an opportunity to "make their research useful to the general public." Not all German eugenicists, before or during the Nazi period, shared Hitler's lethal racism, but many did. Fischer was typical for his collaborative and even participatory stance in relation to Nazi policies.

Notoriously, these would lead to euthanasia and mass murder. The T4 Program, in which doctors and technicians murdered some 70 000 mentally ill and disabled Germans between 1939 and 1941, was the precursor to even larger administrative, technological, and industrialized slaughter during the war. The links between eugenicists and this program, and the later plan to murder millions of Jews and other so-called 'subhumans' in order to eliminate the dangers they posed to the biological health of a greater German and Aryan empire, are not entirely straightforward. Personnel involved in the T4 Program, drawing directly on their previous experiences, helped develop the methods and infrastructure of industrialized killing in the death camps of the Eastern Front, once it became clear that mass murder by shooting and starvation did not work quickly or efficiently enough. Many in the eugenics movement denied that they or their ideas were instrumental in these events. Nonetheless, a number of physicians and scientists, clearly influenced by eugenic ideas and related genetic research, were indeed involved and saw their careers flourish under the Nazis and even in the camps themselves (Dr. Josef Mengele's murderous experiments in Auschwitz being perhaps the most extreme and notorious example). In any case, eugenic policies and these extreme and grotesque crimes partook of the same logic: a desire to divide human beings into 'hereditarily healthy' (and thus desirable) and 'hereditarily pathological' (and thus undesirable) groups. Eugenicists and committed Nazis (when they were not one and the same, which they often were) both sought, sometimes by different means, to promote the existence of the first group, and to isolate, diminish, and eliminate the second.

In France, the 1930s saw a shift among some eugenicists toward accepting a greater degree of restrictive intervention to assure the quality of the population, with quantity relegated as a lesser priority. Adolphe Pinard's efforts in the 1920s aimed at mandating a premarital examination for all French males to assess their genetic suitability for marriage and procreation. The proposal stalled in the legislature for years, but it demonstrated a growing openness to negative eugenic measures. As the 1930s wore on, physicians and others prominent in the eugenics movement advocated immigration restrictions to protect France's biological capital, and some even promoted birth control despite continuing concerns over falling birthrates and their effect on France's international position in an increasingly dangerous Europe. Charles Richet, president of the French Eugenics Society immediately after the First World War, exemplified this new attitude. His *La sélection humaine* (1919) accepted Lamarckian-style environmental factors as having powerful long term effects on species, but also counseled shorter term restrictive measures to improve the race based on the iron laws of heredity. His proposals included the removal and quarantine of the sick, prohibitions on interracial marriage, "the elimination of the mentally deficient" (through neglect, not euthanasia), and the prohibition of marriage for the 'abnormal.' The most internationally famous of French eugenicists, Alexis Carrel, winner of the Nobel Prize in Physiology or Medicine for 1912, spent the bulk of his career in the United States at the Rockefeller Institute for Medical Research. His international best-seller *Man, the Unknown* (1935), contained both positive and negative eugenic ideas, but he was very clear about how, in his view, the unfit burdened society. In one famous passage he suggested "humanely and economically" disposing of criminals and the criminally insane, "in small euthanasic institutions supplied with proper gases."

It is not clear that this one statement in a long and wide-ranging book is enough to place Carrel firmly in the camp of German eugenicists and physicians deeply compromised by their participation in Nazi euthanasia and genocide programs. It is true that extreme negative eugenics remained relatively marginal in France throughout the 1930s, but Carrel's views and career nonetheless reflect well the trajectory of French eugenics after 1940. After Paris fell to the Germans, Carrel met with the head of the collaborationist Vichy government, Marshal Pétain, and agreed to head a new *Fondation française pour l'étude des problèmes humaines*, founded in November 1941. In the occupied portion of France, the German authorities provided the impetus for indigenous French racism and anti-Semitism to be expressed in eugenic terms. The anti-Semitism of the period cannot be reduced to eugenics, but eugenics often provided support and a vocabulary to buttress even the wildest anti-Jewish propaganda and the most sinister anti-Jewish measures. For example, Louis Darquier de Pellepoix, head of the notorious *Commissariat général aux questions juives*, a center for racist and anti-Semitic propaganda, defended the roundup and deportation of Jews as a 'public hygiene' measure. For its part, Vichy France instituted the most enduring eugenic legacy, the final passage, in 1942, of the long-stalled law instituting a premarital exam, which remains in force to this day. Its sponsors proclaimed it as "the first time [that] a eugenic measure appears in French legislation." Even here, though, the largely positive French style of eugenics was in evidence, since the mandate for the premarital exam was embedded in a series of other measures promoting social hygiene and maternal health. Moreover, though the exam was mandatory, it placed no restrictions on the right to marry nor did it require the parties to divulge the results, even if they revealed a serious infectious disease. It was in this sense merely informative, and

sought, in the words of the law's authors, "only to confront the future couple with their conscience and their responsibility." Thus, even under Vichy, French eugenics avoided the hereditary and racial utopianism of extreme negative eugenics, although that vision triumphed on the other side of the Rhine and spread its malign influence throughout much of Europe.

In Europe broadly, the 1930s and 1940s did see an increase in the ability of eugenicists to influence public policy. Great Britain, the original home of eugenics, was largely an exception. The Eugenics Society remained active throughout the period and concerned itself with race mixing, birth control, and even sterilization, but the political and social environment remained inconducive to the implementation of explicitly eugenic measures both inside and outside the context of the state. A number of other European nations adopted sterilization legislation during the 1930s. But this would prove to be the apogee of eugenics in Europe, even in Germany. It was in part because of the triumph of eugenic thinking, married to racism and totalitarian government, in Germany that eugenics saw a slow but sure decline after the end of the Second World War.

Eugenics in Decline

Events in Germany and German-occupied Europe discredited attempts at genetic social engineering, though eugenics really disappeared only slowly and incompletely over the second half of the twentieth century. The 'Doctors' Trial' at Nuremburg in 1946–47 exposed many of the worst medical abuses under the Nazis, and the close collaboration of physicians and scientists in the implementation of the Nazis' racist policies, attempts at biological engineering, and murder. Nevertheless, prosecution for sterilization was difficult because of its technical legality even before the war began, and because the defense could easily point to similar, and similarly ambitious and widespread, eugenic policies and practices in countries like the United States. Some doctors and scientists associated with eugenics and Nazi policies continued to pursue their work and even held important positions in political and academic institutions for decades after the end of the war.

Eugenic thinking and practice also persisted beyond 1945 in many other places in Europe. Vaud, the only Swiss canton to institute legal sterilization, in 1928, continued the practice for decades, officially repealing its legal basis only in 1985. In France, the prestigious *Institut national d'études démographiques* (INED) formed in 1945 from elements of Alexis Carrel's Vichy-sponsored foundation and with some of its personnel. In the immediate postwar period, the population geneticist Jean Sutter (1910–70), at INED, continued to promote eugenic solutions to traditional French problems associated with public health and population. In Great Britain, the Galton Chair of Eugenics at University College London remained a preeminent position in the academic study of genetics, the Eugenics Society continued its work, and eugenic ideas exerted some influence over medical curricula and even social policy. Italian eugenicists reframed their field of interest as 'genetic demography,' continuing to work largely in the same vein as before the war. Sterilizations continued apace in Scandinavia through the 1970s. In Greece, interest in eugenics actually increased after 1945.

Yet these circumstances should not obscure the long-term decline of the movement. As the full extent of Nazi atrocities in the name of biological engineering sank in, reinforced by continuing revelations, eugenics, 'racial hygiene,' and associated projects suffered by association. This was one reason that eugenicists increasingly rebranded their work: genetic demography in Italy, euthenics in France, social or population biology and a host of other terms, some of them certainly legitimate academic or scientific fields in their own right, elsewhere. And eugenics societies and institutes either faded away or changed their names and even research foci. The German Society for Racial Hygiene ceased to exist after the war, the Swedish Institute for Race Biology became a Department of Medical Genetics at Uppsala University in 1959, and the Francis Galton Laboratory for the Study of National Eugenics renamed itself the Galton Laboratory of the Department of Human Genetics and Biometry at University College London in 1963. The British Eugenics Society waited until 1989 to change its name to the Galton Institute, but change it did. Other organizations outside of Europe – in Canada, Hong Kong, Australia, and the United States – changed their names between 1950 and 1973, dropping references to race, hygiene, and eugenics. In particular, the term eugenics became and remains, largely taboo. The major exception to this was the Hellenic Eugenics Society, founded in Greece in 1954. But even formerly eugenic policies shifted in focus, if not in notorious effect. Sterilizations continued into the 1970s in Scandinavia, it is true, and under the same laws inaugurated by advocates of eugenics. But operations decreasingly occurred because of eugenic concerns or motivations, and instead took individual medical problems or voluntary birth control as their primary rationale. By 1977, Denmark, Norway, and Sweden had all repealed eugenic legislation, replacing it with laws allowing for voluntary sterilization. The symbolic end to academic eugenics had occurred much earlier in its original home of Great Britain, with the ascension of Lionel S. Penrose to the Galton Chair in eugenics. He was, in fact, skeptical about the claims of eugenics to the status of science and was openly critical of some of its specific claims. In 1954, he changed the name of the journal founded by Karl Pearson, *Annals of Eugenics*, to *Annals of Human Genetics*, and changed the name of his position to the Galton Professorship of Human Genetics.

It is important to note that the horrors perpetrated by the Nazis and others were not the only factors contributing to the decline of eugenics. The end had come earlier in the Soviet Union, for example. Stalin's hostility to the claims of eugenics as incompatible with socialism and his own visions for a transformed society brought the curtain down on eugenics decisively after he rose to absolute power in 1929. Human genetics in general suffered from association with 'fascist views' in the 1930s, and from Trofim Lysenko's quixotic and deeply destructive crusade against Mendelianism through the 1950s. The Soviet takeover of Eastern Europe after 1945 spelled the end of eugenics there as well. Other factors eroding the authority of eugenics, at least in its most explicit forms, included the discrediting of race as an idea in science and medicine, as well as in anthropological understandings of human characteristics and behavior; a growing awareness of racial injustice propelled by anticolonial and civil rights movements; and increasing skepticism among broad swaths of

world public opinion about absolutist scientific claims and about the potential for harm that often accompanies scientific and technological advances. One must also not underestimate the effect of increasingly sophisticated scientific understandings of the workings of heredity and genetics. In this view, as scientists like Lionel Pearson discovered, the claims of eugenics appear crude and simplistic – not just wrong, but harmfully so.

Legacies, Echoes, and the Future of Eugenics

At the beginning of the twenty-first century, eugenics seems to many to have disappeared from view. In some ways, it is the science that dare not speak its name, in that eugenic concerns lie only in the background of some modern research in the fields of biology, genetics, demography, and public health. Yet this is most often a distant heritage and the personnel and research agendas deeply compromised by close association with eugenics have by now largely passed from the scene. Eugenics now manifests itself as a term of abuse, a way to make sometimes exaggerated (though sometimes not so exaggerated) criticisms of others' social views and political beliefs. Thus the government of Niger condemned a French author's denunciation of that country's high birthrate and extreme poverty as a 'crime,' and his invocation of sterilization as a solution to this global problem, as 'fascist,' declaring that his comments could not be more racist and they praise eugenics. This reaction demonstrates the reverberating legacy of German and other eugenicists' fateful linkage of racism, government action, and social and population policy.

The legacy of eugenics is also present in contemporary Europe because its victims have not disappeared from the scene. This is all the more true since eugenic practices such as sterilization continued up through the very recent past. Individuals sterilized against their will, and often even without their knowledge, have mobilized to force the governments that perpetrated these acts to recognize the injustice and, in some cases, pay reparations. Some efforts have been unsuccessful, as in Switzerland. Sweden has paid damages to victims, but the practice of sterilization, arguably against one's will, has apparently continued. In 2013, 142 transsexuals brought suit against the Swedish government seeking compensation for having been forced to accept mandatory sterilization in order to undergo sex change operations between 1972 and 2012.

Eugenics also often emerges in present-day discussions of prenatal diagnosis, abortion, and individual and medical decisions about reproduction. For many, the question now is not one of states seeking to extend biopower through control over the reproductive activity of individuals and thus over the larger social body, but of individual parents and doctors making choices about reproduction that modern medical science now makes possible. Beyond prenatal diagnosis, some observers see the specter of eugenics in the growing power science exerts in fertility treatment, genetic manipulation, and so-called 'designer babies.' What is still at issue is the core problem that led scientists, doctors, and others in the past to think in terms of race betterment and eugenics, that is, the impulse to make value judgments about life at the most basic biological level, to arrange life hierarchically into categories of greater or lesser degrees of worthiness, and to act accordingly.

Abstract

This article discusses eugenics in the Americas – a scientific ideology that profoundly has affected the history of this region – and identifies common themes and varied examples for comparison. These examples demonstrate the influence of the 'well-born science' on medicine, psychiatry, education, and public policy. This article includes a broad overview of eugenics in South and North America, pointing out areas of differences and commonalities. The chapter also discusses examples of formal eugenics organizations, in their national and pan-American context and the utility of eugenics for its practitioners. The article finishes discussing examples of eugenic practice through immigration policy, *puériculture* programs, and sterilization.

Introduction

From Argentina to Alberta, eugenics as a science and an approach for understanding human populations profoundly has affected the history of the Americas. Despite the great diversity of geography, historical experiences, and human populations that characterizes these two continents, the Americas in the late nineteenth and into the twentieth centuries shared a history of colonialism, unease about indigenous, former enslaved and mixed-race populations, attempts to manage immigration, and social problems associated with growing urban populations. The spread of eugenics, despite its diverse manifestations, responded to this situation. Discussion of eugenics, in terms of both policy and practice, in South and North America offers evidence of the diversity and adaptability of this movement to 'breed better humans.' Although it is impossible to present a complete overview of eugenics in the Americas because of space constraints, this article will approach eugenics through the identification of common themes and present varied examples to offer comparative insights that also indicate the elasticity of the concept. These wide-ranging examples also demonstrate the influence of the 'well-born science' on medicine, psychiatry, education, and public policy.

This article will start with a broad overview of eugenics in South and North America, pointing out areas of differences and commonalities. Next, this article discusses examples of formal eugenics organizations, in their national and pan-American context, and the utility of eugenics for its practitioners. The article ends by looking at examples of eugenic practices through immigration policy, *puériculture* programs, and sterilization.

An Overview of Eugenics in the Americas

In Latin America, eugenics was fed by and grafted onto concerns emerging in the nineteenth century about the racial composition of these new nations, in which 'problem' populations, including indigenous, African-ancestry or mixed-race people, were considered a hindrance to national modernization projects. These concerns about the population mix were compounded with fears that a tropical climate in warm countries, such as Brazil, was inimical to progress and contributed to racial degeneration. Nineteenth-century elites despaired of building modern, productive, civilized nations from such diverse human populations. To improve their populations, countries like Argentina, Mexico, Peru, and Brazil attempted to encourage, with differing degrees of success, European (ideally northern) immigration; public health and education programs responded to these perceptions of a problematic population mix (Hochman et al., 2010, p. 495; Orbegoso, 2012, p. 232). Yet by the early twentieth century, elites also had begun to believe that making a modern nation required some incorporation of these populations. In Chile, for example, questions about national identity emerging from warfare, reflections that were prompted by a centenary of independence, and fears that European immigration undermined the national character, fostered the concept of the 'Chilean race,' which symbolically incorporated the poor, mixed-race, and indigenous populations into the new imagined national stock (Subercaseaux, 2007, pp. 31–32, 63). Across the region, a wave of cultural nationalism shifted depictions of Latin America's non-White populations from being a hindrance to progress to being an essential component of a unique national identity; nonetheless, elites continued to anticipate that African and indigenous elements of the population eventually would be 'whitened' away (Chomsky, 2000, pp. 420–422). The former Mexican minister of education, José Vasconcelos, in *La raza cósmica* (1925) (*The Cosmic Race*), lauded the *mestizo* (originally meaning mixed indigenous and Spanish) as the result of an aesthetic, spiritual eugenics that combined the best aspects of Europeans, indigenous people, Asians, and Africans. Nonetheless, his vision was based on the assumption that the European contribution redeemed this 'cosmic race' (Stern, 2000, pp. 61–62).

Attitudes toward the poor and ethnically diverse populations had begun to shift from the later nineteenth century. Increased urbanization and nascent industrialization, however, brought such issues as contagious illnesses, like tuberculosis and syphilis, alcoholism, infant mortality, labor activism, and unhygienic housing to the attention of the public and medical professionals. Lumped together, these problems were referred to as the 'social question.' Eugenic influences were frequently evident in public health responses to this social question. Nancy Leys Stepan has argued that the version of eugenics that flourished in Latin America, influencing state policies, national debates, public health, and the sciences, was influenced heavily

by neoLamarckian ideas of the inheritance of acquired characteristics (1991, p. 76). Within a neoLamarckian approach, alcoholism, for example, could be seen as a eugenic issue because, although it resulted from social problems, social action to address it would have positive eugenic results. Keeping 'nature' and 'nurture' together united eugenics, public health, and sanitation programs, as any intervention in aspects of 'nurture', over time, could benefit the 'nature' of the national population (Stepan, 1990, pp. 119–122; see also Stepan, 1991, pp. 67–84). Focus on 'nurture' in Latin America meant that puériculture, the scientific cultivation of the child, and homiculture, which turned the puériculture approach to the study of adult life cycles, were both popular manifestations of eugenics evidenced in public, childhood, and maternal health programs (Schell, 2010, pp. 478, 485). But the later shift to Mendelian genetics did not undermine the case for eugenics. Recent research on Brazil has indicated that proponents of Mendelian genetics also supported eugenics, even as they distinguished between problems due to genetic inheritance and social conditions (Hochman et al., 2010, p. 494).

Part of the malleability of eugenics, and its resilience as a concept, was the elasticity and context specificity of defining who was 'unfit' (see Levine and Bashford, 2010, p. 7). Even as ideas of 'better birth,' which underpinned eugenics can be found throughout the Americas, the expression of that sentiment and the populations of 'undesirables' against whom it was directed was highly particular. Bearing this elasticity in mind, Latin American countries offer interesting eugenics case studies, as their populations (usually largely composed of indigenous, African-ancestry, or mixed-race peoples) were considered 'dysgenic,' that is, they reproduced 'undesirable' traits, in Western Europe and the United States. Thus, focus on eugenic policies in their various guides direct us to those sectors of the population that prompted anxiety for the state, the medical professions, educationalists, and journalists, among others.

In Canada and the United States, eugenics was one expression of the new public health movement, stemming from a belief that understandings of heredity could improve the health and welfare of the population at large. Part of this public health movement allowed the discussion of previously taboo topics, such as birth control and venereal disease, under the guise of social reform (McLaren, 1990, pp. 28, 68). Eugenics also built on fears, known as 'race suicide,' that the Anglo-Saxon population was not reproducing quickly enough when compared with other groups, such as immigrants and non-White populations (Roberts, 1997, 60–61; McLaren, 1990, pp. 44–45). Eugenics was adopted readily in Canada and the United States due to widespread notions of scientific racism, which held that biologically existing 'races' had innate, inheritable characteristics that determined capacities. In the United States, theories of scientific racism also justified segregationist policies toward the African-American population (Roberts, 1997, 61). Moreover, as in Latin America, in Canada and the United States, the Aboriginal–indigenous peoples were viewed through a colonial mentality that held that this population represented an obstacle for society's advancement, doubted the intellectual capacities of these peoples, and judged them unfit for modernity (Strange and Stephen, 2010, p. 534). Thus, in these countries, eugenic discourse and practice permeated medicine, public health, immigration policy, and popular culture. Ian Robert Dowbiggin argued that, in Canada and the United States, in the early twentieth century, the profession of psychiatry was so infused with eugenic beliefs that the task of the historian is to "determine the different *shades* of eugenicism" (1997, p. xi; italics in original). That task is appropriate for the Americas at large.

Institutions, Organizations, and Practitioners

One important site for the creation of eugenics knowledge in the United States, which then fed into circulation throughout the Americas, evolved from a research project funded by the Carnegie Institute, in 1904, into the Eugenic Record Office, at Cold Spring Harbor, Long Island. The project was run by University of Chicago professor and biologist Charles B. Davenport, whose team researched the genetic history of extended families believed to be carriers of hereditary abnormalities, evidenced in "laziness, mental retardation, and immoral habits, as well as high fecundity." On the basis of his team's work, Davenport concluded that heredity not only determined instances of diseases, such as hemophilia, but also alcoholism, insanity, and criminality. The Eugenic Record Office trained experts (including 250 field workers) for and supplied research to the growing eugenics movement as well as disseminated findings in such publications as the *Eugenical News* (Roberts, 1997, pp. 61–62. Quotation p. 62).

But eugenics in the United States moved well beyond the Atlantic seaboard (Stern, 2005b). The 1915 Panama Pacific Exhibition, held in San Francisco, offers an interesting example of eugenics beyond the US East Coast, but also as a growing popular science. Simultaneous to the Panama Pacific Exhibition, San Francisco hosted the National Conference on Race Betterment; eugenicists wanted to take advantage of the potential audiences. The Pan-Pacific exhibition's organizers were delighted, as the two events both sought to promote civilization and progress, and they designated one week of the Pan-Pacific Exhibition as 'Race Betterment Week.' The 'Race Betterment Exhibit' at the Pan-Pacific Exhibition sought to prove declining standards of racial health nationally and became one of the most popular displays. For these eugenicists and supporters, 'race betterment' depended in large part on ensuring that middle-class white women took up their social responsibility as women to be mothers who reproduced healthy citizens within marriage. This cementing of selected women's primary social responsibility as home and family came at a time, the 1910s, when new opportunities for women in education, work, and leisure threatened to distract them from their reproductive duties (Kline, 2001, pp. 14–19, 29). Concerns about women and sexuality were fundamental themes to eugenics in the Americas at large.

According to Stepan, the start of organized eugenics in Latin America came a few years later, with the founding, in Brazil in 1918, of the São Paulo Eugenics Society, whose 140 members were almost all physicians. The organization's arguments that linked long-standing public health concerns, such as tuberculosis, alcoholism, and venereal diseases, to the need to make Brazil a eugenic nation, gained positive coverage in the local

and regional press. Although this society lasted only a few years, eugenics approaches and discourse permeated public health discussions and publications (Stepan, 1991, pp. 47–50). In Mexico, a normalization of eugenics was evident at the 1921 Mexican Congress of the Child, which debated maternal health issues and population 'whitening,' as well as narrowly voting in favor of forced sterilization of criminals. By the end of the decade, the Mexican Society of Puériculture, founded in 1929, included a eugenics section that discussed heredity, sex education, and birth control. Interestingly, the founding members of the Mexican Eugenics Society (Mexico City, 1931) were from the Puériculture Society's eugenics wing. The new organization, which also debated sex education, birth control, eugenic procreation, and marital health, drew its membership from high echelons of politics, public health, the judiciary, and criminologists, and its influences were evident in state campaigns against venereal disease and alcoholism, as well as in the 1935 legal requirement for a prenuptial certificate (Schell, 2010, p. 485; Stepan, 1991, pp. 55–58; Suárez y López Guazo, 2000, pp. 5, 7, 11, 13).

In Argentina, formal eugenics emerged after physician Víctor Delfino attended London's First International Congress of Eugenics. Delfino founded the Argentina Eugenics Society in 1918, which made immigration control one of its principal campaigns amid concerns about the impact of immigrants on national culture. By 1932, in a swing to the right, the Argentine Association of Biotypology, Eugenics, and Social Medicine was founded. Close cultural links between Argentina and Italy, a result of that worryingly large-scale Italian immigration, helped account for the inclusion of 'biotypology,' which was an Italian science that posited that "human populations could be divided into distinct types with their own characteristic illnesses and psychological makeup." Understanding biotypology would allow a state to use its human resources most effectively. The association offered training in biotypology's methodologies and diagnostics, including running a clinic for determining biotype and offering appropriate interventions (Stepan, 1991, pp. 58–61. Quotation p. 60).

Although eugenics policies and practice undoubtedly had national manifestations, eugenicists in the Americas formed part of a pan-American movement, most readily evident through international meetings. For example, when the first pan-American Conference on Eugenics and Homiculture was held in Havana in 1927, US eugenicist Charles Davenport, along with his ally leading Cuban eugenicist Domingo F. Ramos Delgado, lobbied delegates to approve a pan-American 'Code of Eugenics and Homiculture,' which mandated classification of all residents of the Americas into categories of 'good,' 'bad,' and 'doubtful' to determine who could marry, have children, and migrate. For Davenport, the code addressed concerns about the racial composition of the US's neighbors, as these potential migrants threatened eugenics efforts within the United States. Other delegates, however, argued against the implication that Latin American populations were dysgenic, and the code was defeated in favor of a homiculture approach to eugenics, which endorsed public health and education measures (Guy, 1998, p. 272; Schell, 2010, pp. 478–479; Stepan, 1991, pp. 178–182). At that same conference, delegates from Latin America voted that each state had the right to control immigration in ways that were appropriate to its own ethnic mix and that would not undermine national sovereignty (Stepan, 1990, p. 134).

By the time Buenos Aires hosted the second pan-American eugenics conference in 1934, the international context had changed, especially with the National Socialist rise to power in Germany (1933). Although the eugenics movement had grown in Latin America, it was situated firmly within preventive medicine, social welfare, and only voluntary measures offering advice on eugenic reproduction. The 1930 papal encyclical *Casti Connubii* (*On Christian Marriage*), condemning eugenics and sterilization, also diminished the influence of 'negative' eugenics, such as sterilization, in Latin America, as well as French-Canada, while strengthening Catholic opposition at that end of the eugenics spectrum (Klausen and Bashford, 2010, p. 105; Stepan, 1990, p. 135; Strange and Stephen, 2010, p. 526). Stepan concluded that the firm marginalization of the US version of negative eugenics at the Buenos Aires conference ended the pan-American eugenic movement (1991, pp. 61, 183–186). But beneath this formal support for 'positive' eugenics in Latin America, historians also have found evidence of negative eugenics practice, discussed later in this article. In the United States and Canada, in contrast, negative eugenics was supported by both policy and practice.

To understand how eugenics came to have such a pervasive influence, Dowbiggin argued that, in the case of psychiatry in Canada and the United States, professional reasons have to be placed at the forefront. As the practice of psychiatrists was largely limited to state asylums and public health organizations, where their work could seem like being glorified guards of incurable patients, eugenics offered a reassuring explanation for psychiatrists' failure to 'cure' institutionalized patients and additionally gave them an excuse to move beyond the asylum (1997, pp. x, 27, 50). McLaren concurred, arguing that for medical doctors in Canada, advances in medical science in the late-nineteenth century, including 'germ theory' (the discovery in this period that microorganisms cause some infectious diseases), improved the status of physicians, who claimed unique knowledge for diagnosing illness and recognizing threats to public health. Eugenicists' arguments that often social and health problems were hereditary, not environmental, further strengthened doctors' professional authority. Meanwhile, the state bolstered the status of medical professionals, turning to these experts to understand and resolve problems associated with industrialization, foreign immigration, urbanization, and low fertility of the Anglo-Saxon population (1990, p. 29). Stepan found parallel transformations in the medical profession in Latin America. The number of doctors increased, their training became more professional and formalized, and they worked in a context in which there were growing expectations that medical science could design successful interventions to stop the endemic diseases decimating populations. In Brazil, for instance, successful public health campaigns against yellow fever, smallpox, and the bubonic plague earned acclaim for the Oswaldo Cruz Institute, which eventually became federally funded, and hero status for its eponymous director (1991, pp. 42–43). These medical heroes contributed new ways to resolve problems associated with segments of the population considered dangerous or threatening.

Targeting the 'Unfit'

Throughout the Americas, gender became one of the major axes around which eugenics rotated: Gender norms, male and female social roles, ideas about normal and abnormal sexuality, and reproduction all have gender at their core. Women's behavior and their procreative choices were of particular concern for eugenicists. Yet the eugenics movements also provided new professional opportunities for middle-class women. Women became both objects for eugenic intervention, and practitioners of eugenics (Kline, 2001, p. 5; see also Stern, 2010).

Multiple examples indicate how eugenics frequently targeted women, particularly because of their role in childbirth and childrearing. In Chile, a 1911 publication by A. Moraga Porras (*Influencia de la cultura física en la formación del carácter. Educación física de la mujer*, or The Influence of a Physical Fitness Culture on Character Formation. The Physical Education of Women), argued that women's physical health mattered more than their intellect because of their procreative role and their responsibility to provide the nation with healthy children who would improve the 'Chilean race' (Subercaseaux, 2007, p. 57). Likewise, in Argentina, the majority of eugenic medical studies were oriented toward women, as there was concern among demographers that population decline was due to women's failure of maternal feeling or eugenic unfitness (Eraso, 2007).

In both Canada and the United States, as will be discussed, concern about the 'inappropriate' sexual behavior of young working-class women, who then were defined as 'morally' unfit, made them vulnerable to eugenic interventions. For instance, in Canada morally unfit women could be committed to the Ontario Provincial Asylum for Idiots, despite the lack of formal eugenic policies as a framework for doing so. A 1924 amendment to the Juvenile Delinquents Act had given the Canadian courts authority to take action to police morality, and young women, Aboriginal or Anglo-Celtic working class, were most at risk of state policing (Strange and Stephen, 2010, pp. 527–528).

In Canada, eugenics also singled out the 'feeble-minded' and immigrants as dangerous for the eugenic nation, giving the state responsibility to act in the national interest. Helen MacMurchy, who had been the first women to earn a medical degree from the University of Toronto, was appointed in 1913 to be Canada's first 'inspector of the feeble-minded.' She blamed the country's 'epidemic' of feeblemindedness on alcoholism, crime, infectious diseases, philanthropy, and immigrants (Strange and Stephen, 2010, pp. 526–527. Quotation p. 527). Eugenic concerns also influenced Canadian immigration policy; a 1906 change to immigration law prohibited the entry of potential immigrants who were feeble-minded or who were morally dubious criminals. This amendment additionally gave the Department of Immigration the authority to deport immigrants about whom fears arose retrospectively. If one medical doctor raised concerns about mental illness, potential mental illness, or moral failings, these concerns constituted grounds for deportation. Mental fitness was not the only grounds for restricting immigration; starting from 1885, immigration legislation included race as a criterion on which entry could be refused. A 1923 federal law explicitly prohibited all Chinese immigrants (Strange and Stephen, 2010, p. 529). Nancy Ordover's argument that, in the United States, anxiety about Mexican immigration resulted from a "dual image of immigrants as both containing foreign bodies, in this instance disease [such as bubonic plague], and constituting foreign bodies within the national entity" (2003, p. 37; italics in original) was also the case in Canada. But controlling immigration was a common eugenic measure in other parts of the Americas: In the late 1930s, the Brazilian constituent assembly voted to restrict immigration by setting racial quotas and tests of fitness for entry; one of the goals of this legislation was to protect the eugenic processes already at work in Brazil (Stepan, 1990, p. 143).

Positive and Negative Eugenics in Latin America

Although immigration controls could limit external dysgenic influences, 'puériculture,' a form of eugenics widespread in Latin America, which inextricably linked mother and child, would help improve the national stock. Puériculture also built on gender stereotypes in which women were given a central role as the mothers of families who made the foundations of a strong state. In Argentina, members of the Association of Biotypology presented a plan to create a state organization for the welfare of mothers and infants, passed by congress in 1936, which resulted in the National Department of Maternity and Infancy. The new department had oversight of eugenic intervention before marriage, before conception, and in pre- and postpartum care, and it responded to concerns about high rates of infant mortality and 'weakening' diseases among the adult population (Eraso, 2007, pp. 793–794, 802–803). In Brazil, as well, where slavery had only been abolished in 1888, eugenicists promoted puériculture and wise marriage choice for young women (Stepan, 1990, pp. 123–124). Mexico, too, embraced puériculture. The Department of Public Health's School Hygiene Service implemented many of the resolutions from the First Congress of the Child, held in 1921, including training women and girls in puériculture, building playgrounds, and sending health visitors to supervise young women (pregnant or not) in Mexico City's poor neighborhoods. Later programs included tracking the progress of local mothers and children, as well as teaching families about basic hygiene. These programs fed into the Mexican Society of Puériculture, mentioned earlier, which was founded in 1929, and the origin of the Mexican Eugenics Society (Stern, 1999, pp. 373–374).

Although eugenics policies in Latin America generally fell into the category of 'positive' action, historians have shown how 'negative' eugenics also influenced practice. In Argentina, although permanent sterilization was banned in principle, the procedure could be carried out legally in cases in which there was a danger to the mother. In practice, this caveat allowed for permanent eugenic sterilizations of women during the 1930s, when a more conservative national mood contributed to greater concerns about population fitness. Interpreting this exception broadly, doctors carried out sterilizations in cases in which pregnancy was believed to complicate existing conditions, such as diabetes or tuberculosis. But there were other cases in which sterilizations were carried out based on less-evident health risks. For instance, in 1928, a leading

obstetrician sterilized a woman who had leprosy, using eugenic reasons as one of his justifications. On the basis of her research, Yolanda Eraso concluded that eugenic sterilizations, presented as procedures on medical grounds, were more practiced than has been recognized and the legal framework offered doctors considerable discretion in performing the operation. At the 1940 Fourth Argentine Congress of Obstetrics and Gynecology, Uruguayan participants were more open about practicing sterilization, which was sanctioned by the Uruguayan Commission of Hygiene (2007, pp. 796, 813–819, 822).

In neighboring Brazil, even as elites feared that the population was too small and too diseased for the national space, psychiatrists, criminologists, and experts in legal medicine discussed sterilization, along with birth control and abortion. One account indicates that the director of the National Insane Asylum had sterilized women patients suffering from 'sexual' illnesses. Largely, however, the conservative Brazilian medical establishment was against sterilization on any grounds (Stepan, 1990, pp. 124–125). Meanwhile, in North America, Veracruz State passed Mexico's only eugenic sterilization law in 1932, but there is no evidence it was ever implemented (Schell, 2010, pp. 485–486). Puerto Rico, a US colony, in contrast, served as an island laboratory for birth control testing, funded by the US federal government, and for widespread sterilization amid eugenic concerns about 'overpopulation,' which had no base in empirical data. By the mid-1960s, an estimated 34% of women of childbearing age had been sterilized. How voluntary these sterilizations were remains subject of debate, but alternative nonpermanent forms of birth control were not available, limiting the choices open to women (Schell, 2010, pp. 481–484; see Briggs, 2002; Ramírez de Arellano and Seipp, 1983).

Further north, however, both the United States and Canada practiced eugenic sterilizations widely and over decades. In Canada, during the 1920s and 1930s, calls for the sterilization of the dysgenic became a nationwide campaign, with the support of leading politicians and business representatives and the Canadian National Committee for Mental Hygiene. There were some critics of the growing influence of eugenics. In 1922, an economist at the University of Alberta, H.S. Patton, complained that the popularity of eugenics was a result of the growing power of "professional experts who sought to control scientifically every aspect of life." Nonetheless, at the University of Manitoba, in the 1930s, V.M. Jackson, author of *Rat Ranching in Manitoba*, taught eugenics problems in his zoology courses. Science took control of many people's private lives when the Western provinces of British Columbia and Alberta passed sterilization laws. In the case of Alberta, the legislation built on farmers' support gained through the logic of stockbreeding. A board was created to review the cases of those about to be discharged from asylums, authorizing sterilization as a preventive measure in cases in which a disability might be passed on to children; and, from 1937, that sterilization could be without the patient's consent. Strange and Stephen compared Alberta's local political culture to the US Deep South, noting there was no oversight of the board; the head of the board (1928–1965) authorized more than 3200 sterilizations, about 60% of which were actually undertaken. During the 1950s and 1960s, Alberta's sterilization rates were higher than California's rates, discussed later, and the statue was not repealed until 1972. Strange and Stephen concluded that, although these sterilization laws were not overtly designed to target particular groups, determined by race, gender, or age, in practice young women of Aboriginal background were most likely to be sterilized, partially due to racism and anxiety about young women's sexual and reproductive morality. In conclusion, Strange and Stephen have expanded on Alexandra Stern's argument that Western eugenics in the United States has particular attributes, finding that the same holds true for Canada (Strange and Stephen, 2010, pp. 530–534; Stern, 2005b; see also McLaren, 1990, pp. 26–27, 95–106. Quotation p. 27).

In the field of eugenic sterilization, however, the United States was such a pioneer that its influence has been traced to later German policies (Thomson, 2010, p. 120). Indiana passed the first US law of sterilization in 1907 prompted by studies of allegedly defective families, and in the context of the public health focus of the Progressive Era. Indiana's law mandated the sterilization of criminals, 'idiots,' 'imbeciles,' and some rapists (Dowbiggin, 1997, p. 77). Two years later, California became the third state to legalize forced sterilization, in asylums and prisons; the legislation was expanded in 1913 and 1917, adding protection for surgeons and emphasizing a eugenic rationale for the procedure. California defined sterilization as a public health measure, undertaken for the state's collective good. By 1921, 80% of sterilizations nationally had taken place in California, in part because, as Stern argued, the state had a broad eugenics movement with supporters from education, medicine, government, and the agricultural sector. In 1927, the Supreme Court sanctioned California's use of eugenic sterilization, in *Buck v. Bell*, drawing on states' rights to vaccinate under public health guises as the legal precedent. With the public health endorsement of the Supreme Court, by 1932, 27 states had passed sterilization laws and 3900 procedures had been performed (2005a, pp. 1129–1130).

In the subsequent decades, California continued to top the nation's sterilization tables, even in per capita comparisons, and the procedure's supporters argued that the practice must be extended beyond the state's institutions. In these state institutions, such as mental hospitals, sterilizations were disproportionately carried out on immigrants and African and Mexican-Americans. Anxiety about female sexuality and gender norms further characterized the procedure; many of the sterilized female patients in their late teens and early 20s had been institutionalized because they were 'promiscuous' or 'nymphomaniacal' for having a child while unmarried (Stern, 2005a, pp.1130–1131).

Men were sterilized, too, but the explanations for sterilizations were gender specific, again indicating how important gender is to understanding eugenics. Wendy Kline argued that, at California's Sonoma State Home for the Feebleminded, from 1918 to 1944 between 56 and 62% of women were sterilized, which was a slightly higher rate than men (she does not give the exact percentage rate for men). Moreover, the reasons given for the sterilizations differed by gender: The women were sterilized to protect society from their allegedly threatening sexual activity, while the men were sterilized for the benefit of their own health. One study, from 1926, estimated that 25% of the young women sterilized had been sent to the Sonoma State Home expressly for the procedure, often because of their expressions of sexuality; they were released after only a few months (2001, pp. 51–54).

Sterilizations in California dropped in the 1950s, as legal changes tightened administrative requirements for physicians and protection for patients increased; nonetheless, well into the 1970s, the procedure continued to be performed at state institutions. Using federal support for family planning and birth control, and also due to a new public awareness of family planning issues, in the late 1960s, California turned its attention to the reproduction of working-class Mexican-American women. Stern argued that in a context in which family planning models endorsed two or three children, increasing resources for birth control, and a lack of standardized consent for sterilization, situations arose in which women had little protection against coercion (2005a, pp. 1132–1133). At Los Angeles County General Hospital, obstetric residents were expected to meet quotas for tubal ligations and, in a two-year period from July 1968, 'elective' tubal ligations rose by 470%. In *Madrigal v. Quilligan*, 10 sterilized women, all Spanish speakers who immigrated to the United States in their teens, worked for low wages, and had been sterilized after difficult births ending in a caesarean, took out a class action lawsuit against the hospital. The lead defendant, obstetrician Edward James Quilligan, had been heard to express eugenic views about Mexican women burdening society by having too many babies. Although the plaintiffs lost, the hospital subsequently improved its compliance with federal guidelines regarding consent in sterilizations (Stern, 2005a, pp. 1134–1135). Stern concluded that in the 70 years its sterilization law was in force, more than 20 000 nonconsensual sterilizations in state-run medical institutions had been performed in California (2005a, p. 1128).

Yet as Roberts argued, the practice of nonconsensual sterilization was not limited to California or to procedures undertaken through eugenics laws: Under the auspices of expanding health care provision, African-American women in the US South underwent nonconsensual hospital sterilizations; one activist estimated that 60% of the African-American women of Sunflower County, Mississippi, had been sterilized postpartum without consent. When the family of two teenagers sterilized without consent in 1973, fourteen-year-old Minnie Lee and twelve-year-old Mary Alice Relf, turned to the Southern Poverty Law Center for redress, the resulting class action lawsuit concluded that federally funded programs had sterilized between 100 000 and 150 000 poor women and girls annually: almost half of them were African-American. Sterilization programs aimed at the Native American population reached an estimated 25% of women; between 1973 and 1976 more than 3000 nonconsensual sterilizations were performed. Roberts concluded that, "eugenic sterilization enforced social judgements cloaked in scientific terms" (1997, pp. 70, 90, 93–95; quotation 70).

Sterilization was not the only way in which the 'unfit' could be prevented from 'harming' the population. Martin S. Pernick has found widespread public support for, and interest in, eugenic euthanasia practiced on newborns, such as a girl born in 1917 who was microcephalic and did not have a complete skull. Her case responded to surgeon Harry Haiselden's publicity campaign about his decisions to deny treatment to 'defective' newborns in the first decades of the twentieth century. To make his case, Haiselden lectured publicly, wrote articles for the *Chicago American*, brought reporters to see the infants and interview their mothers, and collaborated on a fictionalized film based on one case of infant euthanasia called *The Black Stork*. His public stance on the issue brought his actions and those of the parents under legal scrutiny, but despite there being grounds of neglect on which to prosecute, neither Haiselden nor any of the parents were ever charged. By the 1920s, public support for euthanasia had dimmed and supporters of eugenics distanced themselves from infanticide, but the connection reemerged in the 1930s, as some US eugenicists supported German eugenic practices including euthanasia (1996, pp. 4–5, 8, 31, 160–167).

Conclusion

In this brief overview of eugenics in the Americas, despite evident diversity, there are common contextual features and manifestations of eugenics. In all cases, American countries were dealing with postcolonial situations, including ethnically diverse populations that included some combination of African and indigenous peoples. Depending on national demographics, responses to this diverse population differed, but always emerged from a concern, especially in the early twentieth century, that these populations were an impediment to progress and needed to be altered, improved, or eliminated. Immigration was a key issue, as well, both as a eugenic salvation, assuming that the correct people would settle, and potentially as another threat to national health. This overview also made clear how eugenics was a profoundly gendered project, in which women's maternal role and sexuality were polemical areas of state and medical intervention. Through eugenic discourses, the state and medical professionals took it upon themselves to determine what normal sexuality was for women, which women would be encouraged to reproduce or be sterilized, and how to help the right women reproduce a strong nation. Yet although race and gender were important components to eugenics, eugenics singled out 'dysgenic' populations in other ways. The 'feeble-minded,' the alcoholic, the syphilitic, and the poor also were subjected to eugenic interventions. Thus, study of eugenics in the Americas offers evidence for the durability and adaptability of a concept that influenced social and health policy and practice for much of the twentieth century. In Latin America, eugenics appealed in part because it offered a scientific method to foster a 'biologically consolidated nation.' Latin American elites were fearful that their national potential was undermined by lack of unity in culture, purpose, and population, after four centuries of racial mixing (Stepan, 1999, p. 106). Yet eugenics also grafted onto older notions about racial hierarchy, couched as scientific racism in the nineteenth century, appropriate gender behavior, the politics of power, and national identity throughout the Americas. The history of eugenics in the Americas reminds us of the ways in which science can and has served the interests of perpetuating power and powerlessness. The pervasiveness and adaptability of eugenics also serves as a reminder that the history of eugenics remains highly relevant to the present.

Abstract

This article provides an overview of the history of eugenics, from the Greek philosophers to current debates on genetic screening. The historical sources of eugenics are explored next to its modern scientific foundations such as Darwinism and Mendelism. Moreover, various national contexts are highlighted in an attempt to illustrate how diverse eugenics was, both geographically and thematically.

Eugenics is the theory and practice of improving human heredity, typically through control of reproduction. Although the concept is very old, stretching back at least to the ancient Greeks, the modern movement dates to the nineteenth century when Francis Galton, a British polymath and first cousin of Charles Darwin, proposed the term 'eugenics' from the Greek *eugenes*, for 'well-born.' He defined it broadly as "the science of improving stock, which is by no means confined to questions of judicious mating, but which, especially in the case of man, takes cognisance of all influences that tend in however remote degree to give the more suitable races or strains of blood a better chance of prevailing speedily over the less suitable than they otherwise would have had" (Galton, 1883: p. 17). Galton also distinguished between 'positive' eugenics, which promotes breeding by those possessed of superior hereditary qualities, and 'negative' eugenics, which deters breeding by those with physical, mental, or moral defects.

Eugenics before Galton

Abandonment or outright killing of deformed infants was practiced in the ancient world, although both the rationale for and the extent of infanticide are matters of controversy (Roper, 1913; Riddle, 1992). Infanticide of defective infants was common in Sparta and was approved by both Plato and Aristotle; indeed, the latter thought it should be mandated by law. In the *Republic*, Plato describes a utopian state in which the family is replaced by a community of wives and children, and in which reproduction was regulated by the state and its trusted guardians (Cornford, 1941). Plato's eugenic thinking, which was further elaborated in the *Laws*, further influenced the seventeenth-century Dominican monk, Tomasso Campanella. His *City of the Sun* (1623) describes a utopia where children are bred for the good of the commonwealth, and whose inhabitants are scornful of those who neglect the breeding of their own kind. Galton himself wrote a utopian eugenic novel under the title *The Eugenic College of Kantsaywhere* (now digitized and available at http://www.ucl.ac.uk/library/special-coll/ksw.shtml). In addition to philosophy and utopianism, examples of eugenic thinking can also be found in medical literature, including the poem entitled *Callipaedia* written in 1655 by Claude Quillet and the *Essai sur la manière de perfectionner l'espèce humaine (Essay on How to Perfect the Human Species)* published in 1756 by Charles Auguste Vandermonde, and in the writings of nineteenth-century phrenologists and physiognomists, who were fascinated with the hereditary character of disease and mental traits and the implications for reproduction.

From Galton to the 1930s

Charles Darwin and Evolutionary Thought

The publication of Darwin's *Origin of Species* (1859) was central to the emergence of modern eugenics. Darwin argued that evolution occurred through a process of fierce competition in which organisms with advantageous traits would tend to survive and reproduce their kind, while the ill-adapted would leave few if any progeny. He and his contemporaries viewed this process as a progressive force that tended toward the constant physical and mental improvement of organic beings. But many Victorians worried that natural selection was no longer at work since modern medicine, charity, and other humanitarian measures prevented the culling of the physically and mentally weak. Moreover, it seemed as though the worst elements of society were breeding at a much faster rate than the best. Darwin expressed a common middle-class anxiety about the 'differential birthrate' when he remarked in *The Descent of Man* (1871) that if various checks "do not prevent the reckless, the vicious, and the otherwise inferior members of society from increasing at a quicker rate than the better class of men, the nation will retrograde, as has occurred too often in the history of the world. We must remember that progress is no invariable rule." Darwin himself did not advocate any practical measures to counter the alleged degeneration of modern society. But in 1869, his cousin Galton published the first modern eugenics manifesto, *Hereditary Genius*, prompting Darwin to exclaim: "I do not think I ever in all my life read anything more interesting and original" (Galton, 1908: p. 290).

Galton's Argument

Like many Victorian scientists, Galton was interested in a wide range of subjects, from geography to phrenology, and he was also an avid inventor. But his central passion was eugenics. Believing that heredity and not environmental influences could

explain the racial, cultural, and social differences between populations, Galton applied quantitative measurements and analysis of variants in the physical dimensions of the human body to explain social class differentials in British society. Galton aimed to prove that human mental, moral, and temperamental traits, and not just physical ones, were transmitted from parents to offspring. These traits included a gregarious personality; a truthful or courageous character; a liking for alcohol, drugs, or gambling; and a tendency to pauperism, crimes of violence, or fraud. He was particularly concerned to prove the heritability of traits making for social success.

His method was simple. Consulting biographical dictionaries, he established that men who had achieved eminence in various scientific fields were much more likely than others to have had fathers who were themselves eminent; in short, that achievement ran in families. Of course Galton knew that individuals also inherit social advantages, and he conceded that this might explain success in certain fields. No admirer of the landed aristocracy, which still dominated parliament, the army, and civil service, Galton noted that "it is notorious that neither the Legislature nor the army afford, in their highest ranks, an open arena to the ablest intellects" (Galton, 1865: p. 161). But in the 'open fields' of science, literature, and the law, individuals without talent would surely fail, no matter how distinguished their families, while conversely, the talented would succeed, no matter how unfavorable their background.

Unfortunately, it seemed that those with the most talent were the least reproductively prolific. Galton argued that there was an urgent need to reverse this trend. In his view, this could be achieved by convincing those of 'good' stock to marry, preferably with each other, and to have many children. His ideas for inducing the fittest to reproduce included celebrating their marriages in Westminster Abbey, providing state 'dowries' to encourage early marriage, subsidized housing settlements where gifted couples could raise large families, as well as payments to women graduating from college who married before age 26 and on the birth of each child.

Changing Views of Heredity

Galton believed that the hereditary material was transmitted intact from one generation to another. However, his contemporaries – including Darwin – were 'Lamarckians,' who assumed that characteristics acquired by organisms during their lifetime (primarily through the use and disuse of particular organs) could be transmitted to their offspring. The Lamarckian or 'soft' view of heredity blurs the distinction between nature and nurture, since it assumes that inherited traits can be suppressed or redirected by changing the conditions of life. Thus, even if social problems such as criminality, promiscuity, or pauperism resulted from poor heredity, the solution could reside in improved nutrition, education, or other social reforms. But if heredity is impervious to environmental changes, the only way to eliminate the problems it caused would be through selective breeding.

Developments in the burgeoning field of genetics after 1900 were to the development of eugenics what the seminal theory of natural selection was to the development of biology in the nineteenth century. The germ-plasm theory proposed by the German cytologist August Weismann (1834–1914), which rejected the inheritance of acquired characteristics, and the hereditary model proposed by the Moravian monk Gregor Mendel (1822–1884), later known as the system of Mendelian inheritance, changed the course of eugenics. In the new view of heredity, no matter how hard individual parents worked to improve their minds or bodies, or whatever social reforms might be instituted, no child would be born healthier, happier, or more virtuous or intelligent as a result.

Eugenics Becomes Popular

Galton's work initially received a lukewarm reception, especially in the popular press. But after the turn of the century, eugenics caught on. Between 1890 and 1930, eugenics movements of some form developed in over 30 countries, encompassing Central and South as well as North America, Southeast Asia as well as Europe (Adams, 1990; Turda and Weindling, 2007; Bashford and Levine, 2010). By the time the First International Eugenics Congress convened in London in 1912, eugenic ideals had been embraced by more than 400 participants from most European countries and the United States. In Germany, a variant of eugenics called racial hygiene emerged at the end of the nineteenth century, particularly in the writings of Alfred Ploetz. Most German eugenicists, following Ploetz, shifted the focus of eugenics from a Galtonian preoccupation with the individual's inherited qualities to those of the broader national community. Racial hygiene, according to Ploetz, was exclusively concerned with the hereditary qualities of the population, and its aims were twofold: (1) to both increase and further those hereditarily 'superior' individuals and (2) to decrease – if elimination was not possible – those considered racially undesirable (Turda, 2010).

Eugenic societies drew most of their members from the professional middle classes: doctors, anthropologists, lawyers, teachers, social workers, ministers, and so on. To some extent eugenics reflected middle-class anxieties about social and political position. Numerous demographic studies seemed to demonstrate that workers and agricultural laborers had more children than the middle and upper-middle classes, with those living in the worst conditions producing the largest families (actual patterns of fertility are a matter of dispute; see Szreter, 1996). Another concern was the ostensibly rapid increase in the number of 'feebleminded.' In 1910, the American psychologist Henry H. Goddard proposed a three-tiered grading system for mental deficiency. Those with a mental age of one or two he termed 'idiots,' those with a mental age of three to seven 'imbeciles,' and those with a mental age between nine and twelve 'morons' (Zenderland, 1999). Members of the 'high-grade feebleminded' or 'moron' class posed the greatest threat to society because they could not easily be differentiated from normal persons. Unlike idiots and imbeciles, they were often physically fit and attractive, and thus had no trouble either finding mates or producing children. But lacking foresight and self-restraint, and unable to distinguish right from wrong, they easily fell into lives of pauperism, alcoholism, sexual promiscuity, and crime. Exhibits at museums, expositions, and state fairs described the disastrous consequences of allowing reproduction by these defectives to go unchecked.

On the basis of pedigree studies demonstrating the passage of traits in several generations of the same family (such as Goddard's study of the Kallikak family), feeblemindedness was judged to be heritable. According to the best science of the day, feeblemindedness resulted from a single recessive gene. It thus initially seemed that the trait could be eliminated if its possessors were prevented from breeding. By the 1920s, that optimistic assessment was shown to be wrong, since most of the offending genes would be hidden in apparently normal carriers. Policies such as eugenic segregation or sterilization, which targeted only those affected, would thus work much more slowly than previously assumed. But most eugenicists reasoned that even a small improvement of the population was better than none (Paul and Spencer, 1995).

Modern scholarship has challenged the once conventional identification of eugenics with political and social conservatism. As diverse ideologically as it was dispersed geographically, eugenics was embraced by a broad array of professional and political elites. In China, eugenics flourished during the Republican Era, where it was invoked by modernizers in their efforts to counter tradition (Dikötter, 1998). In post-1945 Greece, eugenics was invoked as modern technology of health and social planning. Fabian and other socialist eugenicists turned the concern that the worst were outbreeding the best into a case for social and economic change, arguing that only in a society that abolished economic inequality would it be possible to distinguish genetic value from environmental good fortune (see Kevles, 1995; Paul, 1998). These Left eugenicists criticized the racial and class bias that informed most eugenics movements, arguing that the real problem was the high reproductive rates among the least prudent and foresighted of every class.

Although many eugenicists were socially conservative, sex reformers invoked eugenics in support of access to birth control, legalization of divorce and abortion, and radical changes in gender roles, including expansion of educational and employment opportunities for women (who were often drawn to the eugenics cause; for example, nearly half the members of the British Eugenics Education Society were female). Birth-control advocates argued that access to contraception would allow poor women, of inferior heredity, to voluntarily limit their births. According to the manifesto of the American Birth Control League, authored by Margaret Sanger, "funds that should be used to raise the standard of our civilization are diverted to maintenance of those who should never have been born" (Franks, 2005; Engelman, 2011). (Opponents countered that contraception would be used disproportionately by the middle class.) Even 'free love' or abolition of marriage was promoted on the grounds that marriage was often based on class or other genetically irrelevant factors (Paul, 1995; Hansen, 1996).

Eugenic Measures

Until recently, studies of eugenics focused on Britain and the United States. Since the 1980s, however, the focus has greatly broadened to include Canada, Latin America, Germany, Russia, France, Spain, Scandinavia, Australia, China, and Japan and a number of Central and Southeastern European countries. Eugenics took quite different forms in different places. In some Latin American countries as well as in Italy, Spain, and France, where Lamarckianism was rather strong and Catholicism the dominant religion, concerns with biological degeneration did not result in the introduction of sterilization laws. In France, for instance, the puèriculture (prenatal- and child-care), movement, spearheaded by Adolphe Pinard, stressed the value of breastfeeding and of improved diet and more rest for pregnant women, as well as a premarital examination law to prevent dysgenic unions among those individuals with hereditary defects. In Italy, Nicola Pende proposed the science of *biotypology* as a form of eugenic improvement based on identifying the constitutional types within the nation. Instead of sterilization and segregation, biotypologists promoted medical research (particularly endocrinology), maternal treatment, child welfare, and educational campaigns. In these countries, environmental and hereditary improvement were generally thought to be mutually reinforcing, rather than exclusionary (on France, see Schneider, 1990; on Latin America, see Stepan, 1991; on Italy, see Cassata, 2011; on Argentina, see Gomez Di Vincenzo, 2013).

Furthermore, in Central and Southeastern Europe, eugenicists valued the peasantry as an embodiment of racial fertility and national strength. They praised the rural communities while denigrating the city and urban spaces as degenerate and damaging to the racial health of the nation. Moreover, in some national cases, such as Romania, the size of their ethnic minority populations prompted the state to promote eugenic policies on behalf of the ethnic majority (Turda and Weindling, 2007; Promitzer et al., 2011). Even in North America and the Protestant countries of Europe, eugenics encompassed a wide range of activities. In Britain, moreover, where the modern movement originated, there was no effort to pass coercive legislation (which would have been politically impractical, in part due to the strength of the Labor Party, which viewed eugenics as hostile to workers). Following Galton's lead, the Eugenics Education Society emphasized the need to convince their compatriots of the value of controlling reproduction. Thus, eugenics consisted primarily of education and propaganda, such as the Pauper Pedigree Project, which compiled family trees of typical degenerate families (Mazumdar, 1992).

Coercive eugenic measures were, however, adopted in many countries. Beginning in 1907, when Indiana authorized the compulsory sterilization of 'criminals, idiots, rapists, and imbeciles,' sterilization laws were passed in more than 30 American states, two Canadian provinces, all the Scandinavian countries, Estonia, Germany, and Japan. In the United States, opposition from the Catholic Church, concern that the procedure (vasectomy in men, tubal ligation in women) would promote sexual promiscuity and venereal disease, and especially legal challenges to the constitutionality of state laws, originally limited the number of sterilizations (Reilly, 1991). To address the legal issues, Harry Laughlin, Superintendent of the Eugenics Record Office at Cold Spring Harbor, New York (the center of the organized eugenics movement in the United States), drafted a model law. Its use by the state of Virginia was tested in the 1927 case of *Buck v. Bell*. In his famous decision in that case, Justice Oliver Wendell Holmes wrote: "It is better for all the world if, instead of waiting to execute degenerate offspring for their crime, or to let them

starve for their imbecility, society can prevent those who are manifestly unfit from continuing their kind…Three generations of imbeciles is enough." It is significant that Holmes was a progressive jurist, and that his decision in *Buck v. Bell* was approved by seven other members of the Supreme Court, including his distinguished colleague Louis D. Brandeis, famous for his defense of right to privacy (Lombardo, 2008).

In the aftermath of the case, a dozen states revised existing laws or enacted new ones (with more than half the 60 000 legal sterilizations performed in California). In the United States, concerns about deterioration had been heightened by the results of the mental testing program initiated by the army during World War I. Psychologists tested more than 1.75 million recruits and concluded that nearly half the white draft was feebleminded, with blacks and recent immigrants scoring worst. The testing program thus exacerbated anxiety about the quality of immigrants from Southern and Eastern Europe, whose numbers increased dramatically beginning in the 1880s. The newcomers from Russia, Poland, Italy, and the Balkans were resented for their cultural and linguistic differences, support for big-city political machines, and willingness to work for low wages. Eugenicists added that they were also of poor stock, and that mixing with older stock Americans would produce biological degeneration. In the first decade of the century, Theodore Roosevelt had warned repeatedly that old-stock Americans were losing a desperate 'war of the cradle' with lesser breeds, a theme that recurred frequently in both academic and popular literature (Lovett, 2007). In 1924, President Calvin Coolidge signed into law the Immigration Restriction Act, which restricted entrants from any European country to 2% of the foreign-born of the same national origin recorded in the 1890 census, that is, before the massive influx of new immigrants.

American developments were noted in Germany, where a draft law permitting sterilization with the consent of the person involved or his or her guardian had been drafted at the end of the Weimar Republic. In *Mein Kampf*, Adolf Hitler had characterized National Socialism as 'applied biology.' The Nazi government quickly passed a compulsory law, which extended to a wide range of ostensibly genetic conditions. The law was often praised by non-German commentators for its procedural safeguards (Kopp, 1936). Approximately 400 000 Germans were eventually sterilized under the Nazi regime (Bock, 1986: pp. 230–246). In 1939, the Nazis instituted a euthanasia program aimed at eliminating the 'useless eaters' in mental hospitals.

Neither the sterilization nor euthanasia policies were racially oriented. But soon after the Nazis came to power, they enacted the first of the Nuremberg laws, which forbade Germans to marry Jews and others of 'inferior blood.' Other actions targeting Jews, Gypsies, the offspring of German mothers and black French soldiers, and other reviled groups followed, culminating in the Holocaust. Events in Germany were watched closely in Scandinavia, where many eugenicists were critical of Nazi racism but impressed by the sterilization law. Denmark, Sweden, Norway, Finland, and Iceland passed laws of their own during the 1930s (Broberg and Roll-Hansen, 1996).

Support for sterilization reflected fears about degeneration that were shared by elites elsewhere in Europe and in America. It also reflected the Social Democratic emphasis on communal responsibilities, as well as the view that a state that has taken on the responsibility of caring for its citizens must limit the numbers of those who will burden it. With its objectifying scientific gaze, eugenics contributed to this ideal of a healthy national community, one in which those individuals and ethnic groups who were deemed dangerous to the nation were relegated to institutions and marginal social spaces, traditionally reserved for the elderly and the infirm (Turda, 2013).

Opposition to compulsory sterilization did not necessarily imply the rejection of eugenics per se, as clearly evidenced by the British or Italian cases. In fact, most critics took for granted that mentally deficient individuals should be persuaded or prevented from breeding. The issue was how best to achieve this end. Skeptics variously charged that the laws promoted promiscuity, were ineffective, were based on unfounded assumptions about the heredity of mental defect or criminality, and were inevitably biased in their application. A common concern was that sterilization would provide a cheap substitute for the more desirable policies of segregation, training, and community supervision. Even the Catholic Church – the most powerful foe of sterilization – was not opposed to all forms of eugenics (much less committed to the view that procreation is a private matter), and Catholicism's traditional approaches to contraception, marriage, and family life were sometimes viewed as compatible with eugenic teachings (Muckermann, 1933). In the 1930 encyclical *Casti Connubii*, Pope Pius XI castigated eugenicists' desire to prevent 'unworthy' life as an expression of excessive secularization and of the state's interference in the individual and family's private sphere. But while sterilization was condemned as an illegitimate usurping by the state of power over the bodies of its subjects, eugenics was "accepted, provided lawful and upright methods are employed within the proper limits."

Eugenics after World War II

Although it is often said that eugenics was discredited by its association with Nazi barbarities, the reality is far more complex. In the aftermath of World War II, eugenics was increasingly criticized, but eugenic practices and rhetoric often lingered and for some, the word 'eugenics' retained a positive valence. Most eugenics societies in the West survived the war, including the American Eugenics Society and the British Eugenics Society. In Japan, the Eugenic Protection Law was introduced in 1948 (replacing the 1940 National Eugenic Law), while in Greece the Hellenic Eugenics Society was established only in 1952. In many jurisdictions, including several US states, eugenic sterilizations continued after the war. Indeed, in most Scandinavian countries, they peaked in the late 1940s. Racially oriented sterilizations were performed on Romani women under the Communist regime in Czechoslovakia and between 1996 and 2000 on rural indigenous women in Fujimori's Peru.

In the intellectual discourse of the 1950s and 1960s, claims that eugenics had been discredited *tout court* were challenged by those who believed that the core Galtonian aim of human genetic improvement could and should be defended. In the United States, it was common, especially among scientists, to distinguish a good eugenics – one respectful of individual

liberty, disease-focused, scientifically sophisticated, and uninflected by race or class – from the bad eugenics of the past. However, this effort ultimately failed, and favorable references to eugenics became increasingly rare.

Recently, several philosophers have attempted to rehabilitate both the core ideal and the term, arguing, as had many postwar scientists, that eugenics per se is not objectionable – that racism, class-bias, social conservatism, and violations of individual liberty, while prominent aspects of the history of eugenics, were not constitutive of it (Wikler, 1998; see also Kitcher, 1997; Agar, 2004; Glover, 2006). But in most academic and public discourse, to label a practice as eugenics became *ipso facto* to condemn it. As a result, efforts to oppose a 'good' to a 'bad' eugenics have generally been replaced by efforts to demarcate what *is* from what *is not* eugenics.

European Religion from the Atlantic to the Black Sea

Grace Davie, University of Exeter, Exeter, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The first part of this article considers the relevance of the religious factor to definitions of Europe; it also outlines the major confessional divisions within the continent. The second section introduces a range of factors that must be taken into account in order to understand fully the nature of religion in twenty-first-century Europe. The final section deals with the bewildering variety of church–state relationships in this part of the world; it also contains additional material on Russia.

Introduction

The concept of Europe – whether considered geographically or culturally – is not self-evident. While the Western, coastal edge is clear enough, the distinctiveness of Europe within the Eurasian land mass is less so. The first part of this article considers the relevance of the religious factor to the definitional question; it also outlines the major confessional divisions within the continent. The second section introduces the very varied factors that must be taken into account in order to understand fully the nature of religion in twenty-first-century Europe. The final section deals with the bewildering variety of church–state relationships in this part of the world; it also contains additional material on Russia.

The Religious Boundaries of Europe

The complexities involved in the concept of Europe are addressed in Davies (1996). In the early modern period, the idea of Europe gradually disentangled itself from the concept of 'Christendom,' a process in which the religious factor played a decisive role. Given that the nations of Europe had endured centuries of religious war, they were disinclined to remind themselves of what they were supposed to have in common; the notion of Europe provided a more neutral alternative. A longer historical perspective reveals, however, that Christendom had itself been divided long before the early modern period: between an Orthodox East (centered first in Constantinople and then in Moscow) and a Catholic West (centered in Rome), a dispute that came to a head for a mixture of theological and political reasons in the eleventh century.

A central question regarding Europe's self-understanding is connected to this division: should this or should it not include Russia, an Orthodox and Slavophile state that extends to the Bering Sea? This article will include Russia, but will at the same time emphasize the distinctiveness of the Orthodox parts of the continent. Such distinctiveness takes the form of a markedly different cultural heritage. The nations associated with Western Christianity have, for example, experienced the Renaissance, the Reformation, the scientific revolution, the Enlightenment, and the Romantic revival, and take these pivotal movements for granted. Countries further east have been through an equally formative but entirely different historical evolution. For them, the ebb and flow of Islam have been of greater significance. Indeed, it is possible to argue that the concept of Europe finally gives way to something else at the point where Orthodoxy gives way to Islam, on a line that has fluctuated over centuries and continues, from time to time, to play a crucial and not always peaceful role in the establishment of identities. The 1990s disputes between Russia and Chechnya or between Armenia and Azerbaijan are obvious illustrations. The continuing controversies surrounding Turkey's role in Europe – and, more specifically, regarding Turkey's membership in the European Union – are equally pertinent.

Given its long-term cultural significance, the boundary between Catholic and Orthodox Christianity is more important for understanding Europe's religious life than the much later division between communist and noncommunist Europe. With this in mind, it is useful to introduce the terms 'Eastern' and 'Central' Europe when dealing with the former communist countries. The countries of Eastern Europe (European Russia, Romania, Bulgaria, Serbia, and Macedonia) belong to the Orthodox tradition, whereas the countries of central Europe (the Baltic States, Poland, the former East Germany, the Czech Republic, Slovakia, Hungary, Slovenia, and Croatia) developed within Western Catholicism. It is only in the postwar period that they have been separated from the economic and cultural traditions of the West. The enlargements of the European Union in 2004 and 2007 are easier to understand against this background. The 2004 enlargement was almost exactly coterminous with the Western tradition. The 2007 enlargement extended beyond this. The position of Greece is in some ways anomalous; for a large part of the postwar period, it was the only Orthodox country within the Union. In a much longer time scale, however, the contribution of Greek culture to the understanding of what it means to be European in the Western sense is hard to overestimate. Greek rationalism is a formative factor in European identity.

The border between Eastern and Central Europe is, however, as problematic as any other, for on it are found the Greek Catholic or Uniate churches – those, in other words, which have been received under the jurisdiction of Rome but retain their own ritual, practice, and canon law. In the disputed identities of this part of Europe, moreover, the Uniate churches are of considerable importance (notably in the Ukraine and Belarus). Further south and in a rather different way, Bosnia-Herzegovina has been uncomfortably squeezed between Orthodox Serbia and Catholic Croatia, a situation rendered all

 http://dx.doi.org/10.1016/B978-0-08-097086-8.84009-X

the more complex by the presence of a sizable Muslim population dating from the time of the Ottoman occupation. The 1990s conflagration in the Balkans cannot be understood without taking the religious factor into account.

The subsequent divisions of the West into areas or nations that are primarily Catholic or Protestant (or combinations of the two) are inseparable historically from the emergence of the nation state as the dominant form of European political life. The processes by which such divisions occurred are highly complex, involving economic, social, political, as well as religious issues. Ongoing debates among historians deal with which of these factors were the most important historical determinants and how they fit together. What remains indisputable, however, is the unprecedented upheaval in the ordering of Christian society in the sixteenth century, an upheaval that included the emergence of separate political entities or nation states, some of which expressed their independence from papal interference in the form of a state church.

Part of the ambiguity lies in the understanding of the term 'Reformation.' Does this imply innovation and the breaking of new ground? Or does it involve a return to and rediscovery of primitive excellence? Were those who endorsed the theological changes taking place at this time looking primarily for radical change or for conservative independence? Motives were mixed. The more conservative interpretation, however, was bound to appeal to those political rulers anxious to establish independence from external authority, but with a careful eye on stability within. Both were possible within the Lutheran concept of a 'godly prince.' Sometimes the prince had jurisdiction over a whole kingdom or kingdoms. Such was the case in the Nordic countries, where Lutheranism became embodied in their state churches. Elsewhere the process was far more local and concerned relatively small patches of land. The German case exemplifies the latter, leading to patterns that are not only extant but also influential some 400–500 years later.

The Reformation took different forms in different places. In addition to Lutheranism, parts of Europe – notably the Swiss, the Dutch, the Scots, some Germans, some Hungarians and Czechs, and a small but significant minority of French people – were attracted first by Huldrych Zwingli, but then by John Calvin, toward a more rigorous version of Protestantism. Calvinism was both more radical and more restrained: radical in the sense of a new kind of theology based on the doctrines of predestination and redemption, but restrained in terms of its stringent moral codes. The effect of this particular combination on the subsequent economic development of Europe has provided inexhaustible material for an ongoing debate among historians and sociologists alike.

Broadly speaking, Western Europe divided itself into a Catholic South (Spain, Portugal, Italy, and France, but including Austria, Belgium, and Ireland), a Protestant North (the Nordic countries and Scotland), and a range of 'mixed' countries in between (England and Wales, Northern Ireland, the Netherlands, Germany, and Switzerland). Central Europe exemplifies similar categories, though the geography is rather more complicated. Lithuania, Poland, Slovakia, Slovenia, and Croatia are firmly Catholic; Estonia and (most of) Latvia are Lutheran, and relate closely to their Nordic neighbors (a commonality strongly emphasized as the Baltic republics regained their political independence in the early 1990s); and Hungary and the Czech Republic, finally, are rather more mixed (primarily Catholic but with significant Protestant minorities). In other words, boundaries gradually emerged all over Europe dividing one nation from another, one region from another, and one kind of Christianity from another. Boundaries, moreover, imply dominance as well as difference. Majorities and minorities were, and still are, created depending on the precise location of the line in question.

One final point concludes this discussion: the growing secularity of parts of Europe, noting that the secular (just like the religious) takes different forms in different places. Most striking of all are the low levels of religiousness discovered in Estonia, the former East Germany, and the Czech Republic. It would be unwise, however, to attribute this decline solely to the influence of communism. It derives from a complex mix of long-term historical trends and more recent political events. Ecclesiological factors also play their part. It is clear that the Protestant churches of Central Europe were less able to withstand the pressures of the Soviet bloc than their Catholic neighbors – a fact very largely accounted for by the institutional power of the Catholic Church. Such a statement should not detract from the courage of individual resistors inspired by Protestant ideals.

Patterns of Religion in Modern Europe: Factors to Take into Account

This section draws from a longer article (Davie, 2006) to set out six very different factors that – in contrasting ways – contribute to a better understanding of the place of religion in modern Europe. The crucial point to grasp is that these factors push and pull in different directions. Additional material can be found in Byrnes and Katzenstein (2006), Davie (2000), Jenkins (2009), and Willaime (2004).

The six factors are (1) the role of the historic churches in shaping European culture; (2) an awareness that these churches still have a place at particular moments in the lives of modern Europeans, even though they are no longer able to discipline the beliefs and behavior of the great majority of the population; (3) an observable change in the churchgoing constituencies of the continent, which operate increasingly on a model of choice, rather than one of obligation or duty; (4) the arrival into Europe of groups of people from many different parts of the world, with very different religious aspirations from those seen in the host societies; (5) the reactions of Europe's secular elites to the increasing salience of religion in public as well as private life; and (6) a growing realization that the patterns of religious life in modern Europe should be considered an 'exceptional case' in global terms – they are not a global prototype.

Cultural Heritage

The starting point concerns the undisputed role of the historic churches in shaping European culture, bearing in mind that other factors (notably Greek rationalism and Roman organization) also contributed. One example will suffice: the Christian tradition has had an irreversible effect on the shaping of time and space in this part of the world. Both week and year follow the Christian cycle, even if the major festivals of

Christianity are beginning to lose their resonance for large sections of the population. The same is true of space. Wherever you look in Europe, there is a predominance of Christian churches, some of which retain huge symbolic value. This is not to deny that in some parts of Europe (notably the larger cities), the skyline is becoming an indicator of growing religious diversity. Europe is evolving, but the legacies of the past remain deeply embedded in both the physical and cultural environment.

Historical Legacies: The Old Model

Physical and cultural presence is one thing; a 'hands-on' role in the everyday lives of European people is quite another. Commentators of all kinds agree that, with very few exceptions, the latter is no longer a realistic aspiration for the historic churches of Europe. That does not mean, however, that these institutions have entirely lost their significance as markers of religious identity. These ambiguities will be explored in two ways: first, through the notion of 'believing without belonging'; and, second, through the concept of 'vicarious religion.'

One of the most striking features of religious life in contemporary Europe is the mismatch between different measurements of religiousness. There exists, first of all, a set of indicators that measure firm commitments to (1) institutional life and (2) credal statements of religion (in this case, Christianity). These indicators, moreover, are closely related to each other insofar as institutional commitment both reflects and confirms religious belief in its orthodox forms. The believing Christian attends church to express his or her belief and to receive affirmation that this is the right thing to do. Conversely, repeated exposure to the institution and its teaching necessarily disciplines belief.

No observer of the current religious scene disputes these facts – that is, that these dimensions of European religion are both interrelated and in serious decline. There is, however, considerable debate about the consequences of this situation. The complex relationship between belief (in a wider sense) and practice is central to this discussion, for it is clear that a manifest reduction in the 'hard' indicators of religious life has not, in the short term at least, had a similar effect on rather less rigorous dimensions of religiousness. For the time being, the latter remain relatively strong (the data are clear on this point). It is precisely this state of affairs that is captured by the phrase 'believing without belonging,' the popularity of which in both pastoral and sociological accounts of religious life in modern Europe indicating its perceived accuracy.

The connections between emerging patterns of belief and the institutional churches are, however, complex. Not only do the latter continue to exist, they quite clearly exert an influence on many aspects of individual and collective lives in Europe. The notion of vicarious religion is helpful in this context. By 'vicarious,' I mean the notion of religion performed by an active minority but on behalf of a much larger number, who implicitly at least not only understand but also approve of what the minority is doing (Davie, 2007). The first half of the definition is relatively straightforward and reflects the everyday meaning of the term – that is, to do something on behalf of someone else (hence the word 'vicar'). The second half is more controversial and is best explored by means of examples. Religion can operate vicariously in a wide variety of ways. Churches and church leaders perform ritual on behalf of others, notably the occasional offices – and if these services are denied or inappropriately handled, this causes offense and criticism. At the same time, church leaders and churchgoers embody moral codes on behalf of others, even when those codes have been abandoned by large sections of the populations that they serve. Churches, finally, can offer space for the vicarious debate of unresolved issues in modern societies. They are, for example, expected to contribute to – though not dominate – the moral issues of our time, be they bioethical, socioeconomic, or geopolitical.

From Obligation to Consumption: An Emerging Market

That said, Europe's diminishing but still significant churchgoers – those who sustain the tradition on behalf of the people described in the previous section – are beginning to behave differently. Here an observable change is clearly taking place, best summarized as a shift from a culture of obligation or duty to a culture of consumption or choice. What was once simply imposed or inherited becomes instead a matter of personal choice. People go to a church (or another religious organization) because they want to, maybe for a short period or maybe for longer, but there is no obligation on the part of Europeans either to attend a place of worship in the first place or to maintain a connection that no longer meets a need.

As such, this pattern is entirely compatible with vicariousness: the churches need to be there in order that people may attend them if they so choose. The nature of the relationship, however, gradually alters – a shift that is discernible in both practice and belief, not to mention the connections between them. There is, for example, an easily documentable change in the patterns of confirmation in the Church of England (confirmation is the Christian rite of passage denoting full or adult membership in the Church). The overall number of confirmations has dropped dramatically in recent decades, evidence once again of institutional decline. In England, though not yet in the Nordic countries, confirmation is no longer a teenage rite of passage, but a relatively rare event undertaken as a matter of personal choice by people of all ages. As a result, there is a very marked rise in the proportion of adult confirmations among the candidates overall – by no means enough, however, to offset the fall among teenagers. Baptism is following a similar trend. No longer the norm in England, it is becoming increasingly a matter of choice on the part of churchgoing parents on behalf of their children. It is, therefore, more likely to signify membership of a voluntary community than allegiance to a national identity. For all these reasons, the rite itself is changing in nature. It is important to remember, however, that patterns of religion in Europe vary markedly from place to place. In a number of countries (notably the Nordic countries, Poland, and parts of Southern Europe), a very high proportion of children will still be baptized as infants into the majority (national) church.

The situation can be summarized as follows: a new model of religiousness is gradually, if unevenly, beginning to assert itself across the continent. And if the form of religion captured by the term 'vicarious religion' is in effect a public utility, the new model is more like a market – in which there are gainers

and losers (see Davie, 2006). Both models, however, will continue to exist for the foreseeable future: each fills the gaps left by the other. Broadly speaking, the public utility caters for the passively religious among Europeans (the majority), and the market for the more active minority. In this sense, the market lies over the public utility rather than replacing it.

New Arrivals

The fourth factor concerns the growing number of new arrivals in almost all European societies. There have been two stages in this process. The first was closely linked to the urgent need for labor in the expanding economies of postwar Europe – notably in Britain, France, West Germany, and the Netherlands. The second wave of immigration occurred in the 1990s and included, in addition to the places listed above, the Nordic countries, Ireland, and the countries of Mediterranean Europe (Greece, Italy, Spain, and Portugal) – bearing in mind that many of these places, until relatively recently, have been countries of emigration rather than immigration. Unsurprisingly, the situation changed again following the 2008 financial crash.

Both waves of immigration were economically motivated; the implications for the religious life of Europe were nonetheless considerable – bearing in mind that they vary from place to place, depending on both host society and new arrivals. Britain and France offer an instructive comparison. In Britain, immigration has been much more varied than in France, both in terms of provenance and in terms of faith communities. It is important to remember that a significant proportion of British immigrants come from the West Indies and West Africa and is Christian in origin; these people are, moreover, far more formed in their faith than most British people. Britain is also a country where ethnicity and religion crisscross each other in a bewildering variety of ways (only Sikhs and Jews claim ethno-religious identities). In France, conversely, immigration has been largely from the Maghreb; as a result, France has one of the largest Muslim communities in Europe (circa 5 million) – an almost entirely Arab population. Rightly or wrongly, 'Arab' and 'Muslim' have become interchangeable terms in popular parlance in France.

Beneath these differences, however, lies a common factor: the growing presence of other faith communities in general and of the Muslim population in particular is challenging some deeply held European assumptions (Nielsen et al., 2009). The notion that faith is a private matter and should, therefore, be proscribed from public life – notably from the state and from the education system – is widespread in Europe. Conversely, many of those who are currently arriving in this part of the world have markedly different convictions, and offer – simply by their presence – a challenge to the European way of doing things. As a result, European societies have been obliged to reopen debates regarding the place of religion in public as well as private life: hence the heated controversies about the wearing of the veil in the school system, about the rights or wrongs of publishing material that one faith community in particular finds offensive, and about the location of 'non-European' religious buildings. There have been moments when a lack of mutual comprehension, together with an unwillingness to compromise on many of these issues, have led alarmingly fast to dangerous confrontations, both in Europe and beyond.

Secular Reactions

Such episodes raise a further point: the extent to which the secular elites of Europe use these events in order to articulate alternatives – ideological, constitutional, and institutional – to religion. It is important to remember, however, that such elites, just like their religious counterparts, vary noticeably from place to place. Once again, the contrast between Britain and France is helpful, noting that the process of secularization has taken place differently in each case (Martin, 1978).

What in Britain, and indeed in most of Northern Europe, occurred gradually (starting with a declericalization of the churches from within at the time of the Reformation) became in France a delayed and much more ideological clash between a hegemonic, heavily clerical church and a much more militant secular state. This became known as 'la guerre des deux Frances' (the war of two Frances), which dominated French political life well into the twentieth century. Its legacies still remain in the form of a self-consciously secular elite and a lingering suspicion concerning religion of all kinds – the more so when it threatens the public sphere. The fact that these threats are no longer Catholic but Muslim does not alter the underlying reaction. The quintessentially French concept of *laïcité* is deployed both to describe and to justify this approach (*laïcité* is a French term that implies the absence of religion from the public sphere). In Britain, something rather different has happened: overlapping elites (both religious and secular) demonstrate a greater propensity to work together in order to encourage mutual respect between different world faiths. Their goals, moreover, are distinctive: they are more likely than their French counterparts to look for a solution to a particular problem, than to establish a principle (such as *laïcité*) and apply this strictly to all cases.

That said, Britain now plays host to some aggressively secular voices. Resurgent religion brings with it resurgent atheism, a fact that is increasingly noticeable. The group that has become known as the New Atheists may not be all that numerous, but they have been active in public debate. The New Atheists claim that religion should not simply be tolerated but should be countered, criticized, and exposed by rational argument. Leading members include Richard Dawkins, Daniel Dennett, Sam Harris, and the late Christopher Hitchens. It is important to remember, however, that New Atheists stand out even among secularists. The reason is straightforward: unbelief is as diverse as belief and can be placed along a continuum ranging from the mildly agnostic to the ideologically committed. Unbelief, moreover, is unevenly spread across the continent. It is noticeably more common in Northern Europe than the South, and further East it is colored by the legacies of communism. The study of the secular (both in Europe and elsewhere) is increasingly emerging as a subject in its own right. Central to this development is a growing awareness that the religious and the secular are intimately linked; they constitute two sides of the same coin.

Europe as an Exceptional Case

So far, we have looked at Europe from within. Davie (2002) takes a further step, reversing the 'normal' question: instead of asking what Europe is in terms of its religious existence, it asks what Europe is not. It is not a vibrant religious market such as

that found in the United States; it is not a part of the world where Christianity is growing exponentially, very often in Pentecostal forms, as is the case in the Southern Hemisphere (Latin America, Sub-Saharan Africa, and the Pacific Rim); it is not a part of the world dominated by other faiths, but is increasingly penetrated by these; and it is not, for the most part, subject to the violence often associated with religion and religious difference in other parts of the globe – the more so if religion becomes entangled in political conflict. Hence the inevitable, if for some disturbing, conclusion: the patterns of religion in modern Europe, notably its relative secularity, might be an exceptional case in global terms.

Such a statement goes straight to the heart of an urgent and as-yet-unresolved question: is secularization intrinsic or extrinsic to the modernization process? In other words, is Europe secular because it is modern (or at least more modern than other parts of the world), or is it secular because it is European and has developed along a particular pathway unlikely to be repeated elsewhere? The latter seems the more likely case.

Church–State Relationships

A broad-brush profile of religion in Europe provides the background for a more detailed discussion of church and state relationships; these in turn constitute the parameters within which religious life on a national level takes place. Once again, it is helpful to draw on the framework established in Martin's seminal work on the development of secularization (Martin, 1978). Following Martin, Europe is a unity by virtue of having possessed one Caesar and one God (the legacy of Rome); it is a diversity because of the existence of nations. The patterns of European religion derive from the ongoing tensions and partnerships between religion and the search for national integrity and identity. These tensions and partnerships have resulted in a wide variety of church–state relationships within the continent as a whole (Madeley and Enyedi, 2003).

In Western Europe, such relationships range from the state churches of Northern Europe, through the pillarized (politico-denominationally differentiated) cultures of the Netherlands and Belgium, to the considerable diversity contained within the United Kingdom and Ireland (including a Calvinist national church in Scotland, an Anglican establishment in England, assorted nonconformity in Wales, and a technically secular but heavily Catholic state in Ireland). Germany is a biconfessional state in which both the Lutheran and Catholic churches remain important public bodies. Latin Europe includes the privileged Catholic churches of Italy, Spain, and Portugal and the rather different situation in France (the only European nation with a rigorously secular school system in addition to the state itself). In this part of Europe, and especially in France, anti-clericalism has played a historically important role.

In Eastern and Central Europe, it is necessary to start with the autocephalous churches of Orthodox Europe, all of which have been closely aligned with political power over centuries ('autocephalous' means self-governing, that is, churches whose leaders do not report to a higher-ranking authority such as the Pope). In Central Europe, there are examples (notably Poland) of the Catholic Church becoming the effective carrier of an alternative memory during the communist period; elsewhere – in Hungary and Czechoslovakia – the churches were more compromised. For reasons already explained in this article, the Lutheran churches in, for example, Estonia and the former East Germany all but collapsed altogether. Throughout the region, post-communism has brought a new set of challenges in terms of church–state relationships and the associated privileges of either party. Initial euphoria following 1989, often centered on the national church, has in many cases given way to acrimony as disputes over power and property prove difficult to resolve. The collapse of Yugoslavia is a special case; in this part of Europe, national and confessional differences reinforce each other. Both have been sharpened by recent conflict.

Church, State, and Religion in Russia

Russia has been predominantly Orthodox for more than 1000 years, an anniversary celebrated in 1988 – a date that marked a turning point in the fortunes of the Russian Orthodox Church. After seven decades of official atheism, government-sponsored events took place to mark the millennium, and a number of churches and monasteries were allowed to reopen. Several factors are important in this connection. The first is to appreciate the long-term and deep-seated connections between church and state in Russia. Russian Orthodoxy is a prime example of an autocephalous church; founded in 988, it acquired its own Patriarchate in 1589. Its influence was immense, especially when the tsar was weak. At the end of the seventeenth century, under Peter the Great, the balance of power shifted. The Church was subjugated to imperial power, but its links with the state persisted. Both were victims of the Revolution in 1917. For the next 70 years, the Church became the target of Soviet repression. The level of persecution varied over the period, but was at times intense – under communism, the Russian Orthodox Church experienced huge losses of personnel, land, and property. It is worth noting that the destruction of the Church (indeed, of religion more generally) began two generations earlier in the Soviet Union than it did in Eastern or Central Europe. Indeed, parts of the latter experienced a formative period of democracy in the interwar period.

The situation following 1989 should be seen in this light. Given the extent of its persecution under Soviet rule, Orthodox Christianity returned to Russian society astonishingly fast, symbolized in the rebuilding of the Cathedral of Christ the Savior in Moscow. Increasingly, however, the Orthodox Church has become a focal point for both nationalists and conservatives, so much so that a close alliance between the government and the Russian Orthodox Church has become a defining characteristic of Vladimir Putin's tenure. The wheel has turned full circle (Marsh, 2011). An important consequence of this situation concerns the ambiguous status of other faith communities, including the Orthodox churches that place themselves under the Ecumenical Patriarchate in Constantinople rather than Moscow. The Orthodox Church in Estonia is a case in point. Relationships with the Catholic Church remain tense, and a number of Protestant groups have encountered bureaucratic restrictions.

The Muslim population in Russia is relatively young and is expected to grow. It is largely an ethnic religion and is concentrated in the nationalities of the North Caucasus and among the Tatars and Bashkirs of the Volga basin. The situation

concerning Jews continues to evolve. Historically, the Russian Empire hosted the largest population of Jews in the world. Persecution and pogroms led to mass emigration in the late nineteenth and early twentieth centuries, the majority going to the United States. Following 1989, there has been a further exodus – large numbers have left for Israel, the United States, and Germany. The recent renaissance of Judaism in modern Germany is very largely due to this relocation.

Concluding Remarks

The Europe that is emerging as the twenty-first century develops is a rapidly changing place. From a religious point of view, one of the most significant evolutions is undoubtedly the increasing representation of faiths other than Christian. Analytical concepts must evolve accordingly. European religion is giving way to the 'religions of Europe,' a continent that now houses a significant representation of Muslims, Sikhs, Hindus, and Buddhists in addition to the Jewish communities that have played such a crucial role in Europe's recent history. Bearing this in mind, it is clear that the tensions between unity and diversity articulated by Martin more than 30 years ago remain central, though in forms that are peculiar to late modern rather than early modern European society.

It is clear, moreover, that two rather different things are happening at once. On the one hand, the process of secularization continues, though more so in some parts of Europe than in others; on the other hand, religion has returned – somewhat unexpectedly – to the public sphere. The combination is hard to handle. At precisely the moment when they are most needed, Europeans are losing the vocabulary, tools, and concepts that they require in order to have an informed conversation about faith. The result all too often is an ill-informed and ill-mannered public debate about issues of extreme importance to the democratic future of the continent.

European Union Law

Abstract

The European Union is the result of a unique attempt at international integration. While other integration movements have always relied on a continuous political affirmation of integration by the participating states, the European Union is characterized by a transfer of sovereign rights of legislation, execution, and adjudication to central institutions. At the same time, the Treaty of Rome has introduced the legal framework of a common market, providing for individual rights and obligations of citizens in the whole Union. This article sets out the basic legal structures of the Union and the Common Market, the types of legal instruments and their essential effects, and the efforts undertaken to harmonize national legal systems.

The European Union was established by the Treaty on European Union (TEU), signed by the members of the European Community (EC) at Maastricht, Netherlands, on 7 February 1992 (Official Journal of the EC – OJ – 1992 C 224/1). It initially related to three areas commonly called the pillars of the Union: the economic communities (see below), the common foreign and securities policy, and cooperation in the fields of justice and home affairs. They were consolidated by the Treaty of Lisbon of 13 December 2007 (OJ, 2007 C 306). Following the Treaty of Lisbon, the foundational law of the Union can be found in three instruments: the TEU, the Treaty on the Functioning of the European Union (TFEU), and the Charter of Fundamental Rights (consolidated versions in OJ, 2010 C 83).

Historically, the Union is rooted in three communities – which were often thought to be one community, but which were in fact three communities – with different focuses: the EC which was established as the European Economic Community by the Treaty of Rome on 25 March 1957 (United Nations Treaty Series – UNTS vol. 298, p. 11); the European Coal and Steel Community (ECSC) established by the Treaty of Paris on 18 April 1951 (UNTS vol. 261: p. 140); and the European Atomic Energy Community (EURATOM), established by a separate Treaty of Rome on 25 March 1957 (UNTS vol. 298: p. 167). These communities, which formed the first pillar of what became the European Union, were invested with supranational powers of legislation, execution, and adjudication, which they received by transfer from the member states; these powers were exercised by the organs of the communities. Alongside this first pillar, the second and third pillars of the European Union were constituted by policies and forms of intergovernmental cooperation in the fields of 'common foreign and security policy' and 'cooperation in the fields of justice and home affairs,' renamed 'Police and Judicial Cooperation in Criminal Matters' by the Treaty of Amsterdam on 2 October 1997 (OJ, 1997 C 340/1). While the three communities were set up by six founding member states (Belgium, France, Germany, Italy, Luxembourg, and the Netherlands), later accessions (Austria, Denmark, Finland, Great Britain, Greece, Ireland, Portugal, Spain, and Sweden) made the Community grow to 15 member states; a further extension of the Union toward 12 states in central and eastern Europe was put into effect in 2004 (Cyprus, the Czech Republic, Estonia, Hungary, Latvia, Lithuania, Malta, Poland, Slovakia, and Slovenia) and 2007 (Romania and Bulgaria). Croatia became the 28th member state in 2013. The success of this integration is almost entirely due to the transfer of sovereign powers to the three original communities and in particular to the EC. The remainder of this article will therefore deal only with that part of the law of the Union which can be traced back to a transfer of sovereign powers, i.e., with Community Law in the traditional sense. The terms 'Union' and 'Community' will be employed interchangeably.

A Union Based upon the Rule of Law

As the Court of Justice of the European Union has repeatedly held, the European Union/Community is a "Community based on the rule of law, in as much as neither its Member States nor its institutions can avoid a review of whether the measures adopted by them are in conformity with the basic constitutional charter, the Treaty" (Case C-2/88 Imm. – *Zwartveld* – (1990) European Court Reports (ECR) I – 3365 para. 16). In comparison with previous models for the peaceful cooperation and integration of states, the Community approach is outright revolutionary. While political considerations and diplomacy still have a great impact on the settlement of conflicts between member states, national sovereignty is no longer unlimited. States have to respect the law of the Union, lest violations are ascertained by the Court of Justice. Access to the Court is not limited to authorities of member states and the institutions of the Union; legal proceedings may also be commenced by private parties in some cases and generally by national courts of law, which request a preliminary ruling concerning the interpretation or the validity of acts of the Union (see art. 267 TFEU). The enforcement of the law of the Union is thus indirectly entrusted, beyond national governments, to the great number of national judges. While a change of government policy often threatens the performance of international obligations which states have assumed under traditional treaties, the law of the Union is much more stable due to its decentralized enforcement. An agreement among some, or even all, governments of member states not to comply with a specific legislation of the Union would fail sooner or later, unless it was embodied in an amendment of the basic Treaty. Treaty

 http://dx.doi.org/10.1016/B978-0-08-097086-8.86030-4

amendments, in turn, have to be ratified by the parliaments of all the member states (i.e., the Union has no supranational powers here). The repercussions for national policies are apparent: member states are compelled to conduct their policies within the institutions of the Union. The pursuit of a separate policy outside that framework is not entirely excluded but will often meet with opposition from Community Law and the agencies called upon to enforce it. Within the institutions of the Union it is, however, almost impossible for a state to continuously pursue a separate policy. Thus, the rule of law established by the Treaty of Rome has narrowed the political margin of discretion left to the member states, and has channeled their policies toward integration.

Institutions

Under art. 13 TEU, the tasks of the Community are carried out by seven institutions: the European Parliament, the European Council of the Heads of State or Governments, the Council (of ministers responsible for the various branches of government), the Commission, the Court of Justice, the European Central Bank, and the Court of Auditors.

In the legislative process of the Union, only the European Parliament, the Council, and the Commission are involved. While the traditional model of Western constitutions provides for a separation of legislative and executive powers between Parliament and Government, the respective roles of the three European Institutions are more complicated.

The 'Commission' may originally have been conceived as a kind of European executive to implement the integration program of the Treaty. But this task implies wide margins of political discretion, concerning both the priorities and the content of the measures to be adopted. Moreover, the Commission is the only institution which is entitled under the Treaty to initiate legislative proceedings. It is therefore a political heavyweight in the integration process. The governments of the member states each have the right to nominate one member to the Commission, who is, however, completely independent in the performance of his or her duties (see arts. 245 s. TFEU).

It is up to the Council to represent the interests of member states within the Union. The Council consists of a representative of each member state. While each representative may veto a decision where unanimity is required, the votes of the Council members are weighted in accordance with the size of the member state, where the Treaty requires a decision taken by qualified majority (see art. 16 para. 4 TEU and art. 238 TFEU). The Treaty of Lisbon has introduced the so-called enhanced cooperation, whereby a minimum of nine member states may establish areas of advanced integration or cooperation, and this area of cooperation must be open for subsequent access by other member states; enhanced cooperation requires prior permission granted by an act of the Union (see art. 20 TEU and arts. 326 s. TFEU).

The European Parliament initially was named the Assembly and had very little weight in the legislative process, its rights being limited to mere consultation. Since then, various amendments to the Treaty have improved the European Parliament's legal status and thereby increased its political weight. At present, its members are elected by direct universal suffrage (art. 14 TEU); however, much greater relative weight is granted to the votes stemming from small member states like Luxembourg or Malta than to those originating in large member states like Germany. While the rights of the Parliament are still limited to a mere consultation in some areas such as immigration policy (cf art. 77 para. 3 TFEU), most legislative acts now have to be approved by both the Council and the Parliament in the so-called ordinary legislative procedure under art. 294 TFEU. The Parliament still lacks the power to initiate legislation by its own volition.

Legislative Powers of the Union

The Union has no inherent powers, it can only act within the limits of the powers conferred upon it by the member states in the Treaty (cf art. 5 para. 2 TEU). Nevertheless, the effect of that limitation is mitigated by three factors: first, the Court of Justice interprets the empowering provisions of the Treaty in a wide manner; second, the Treaty contains provisions like art. 352 TFEU that confer upon the Union an open-ended power; and third, by the doctrine of implied powers, the Court of Justice has extended the Union's powers even beyond the limits imposed by the Treaty to international commitments insofar as they help to protect the uniform application of the legislation of the Union vis-à-vis third states (Case 22/70 – ERTA – (1971) ECR 263 para. 28).

The exercise of the Union's competence is further limited by the principles of subsidiarity and proportionality (see art. 5 para. 3 and 4 TEU). The legal significance of the principle of subsidiarity is rather limited as compared with its sweeping use in political discussions. It does not relate to the objectives of a legislative action of the Union, which have to be established in conformity with the Treaty by the political institutions. Subsidiarity pertains only to the question of whether such objectives can be better achieved by the Community than by the member states – the so-called comparative efficiency test. It is highly questionable whether the Court of Justice is in a better position than the political institutions of the Community to decide upon that issue. This may be different in the case of the principle of proportionality, which prohibits the Community from taking action that goes beyond what is necessary to achieve the objectives of the Treaty. In the context of the basic freedoms (see Section Principles of the Internal Market), the Court of Justice has, in fact, frequently assessed the proportionality of national restrictions imposed by member states. In the future, better protection of the principles of subsidiarity and proportionality may be effected by the Protocol Two annexed to the Treaty of Lisbon, which grants certain procedural rights to the national parliaments of the member states.

Sources of Union Law

It is common to distinguish the primary and secondary or derivative law of the Union. The primary law of the Community consists of the founding treaties indicated in the introductory paragraph of this article and of some additional international conventions. Moreover, the general principles

common to the laws of the member states are sometimes classified as part of the primary law. These general principles are explicitly referred to in art. 340 para. 2 TFEU in the context of the noncontractual liability of the Community for damage caused by its institutions or by its servants; however, the Court of Justice considers the general principles as a source of law even outside that field and has recourse to them in other matters, too. However, if the distinction between primary and secondary sources of law indicates a ranking, it would appear that only certain general principles such as fundamental rights can actually count among the primary sources of Union law. Whatever the status of the general principles may be, they allow for the flexibility that every legal system needs in order to adjust to new and unforeseen facts and situations.

Art. 288 TFEU lists five types of *secondary sources* of the law of the Union: regulations, directives, decisions, recommendations, and opinions. While recommendations and opinions are not binding, most Union acts are adopted either in the form of regulations or directives. Regulations are directly applicable in all member states, which means that the Union can impose obligations on and grant rights to the citizens of the member states without the intervention of national legislatures. In contrast, a directive is binding only upon the specific member state to which it is addressed, and only to effect the result to be achieved; in order to be applicable to the citizens of the Community, it requires implementation, which can be carried out by the member states in accordance with the forms and methods of their legal system (see art. 288 para. 3 TFEU). It soon turned out that member states were sometimes slow or reluctant to implement directives. In a long line of cases, the Court of Justice has, therefore, extended the scope of directives. National laws, even if enacted prior to a directive, have to be interpreted so as to conform with it (Case 14/83 – *von Colson* – (1984) ECR, 1891 para. 26); insofar as the directive is sufficiently precise and deals with 'vertical' relations involving the defaulting member state, it may even be applied directly by the national courts and authorities (Case 8/81 – *Becker* – (1982) ECR 53 para. 24 s.). While such a direct effect is not admitted in 'horizontal' relations (Case C-91/92 – *Faccini Dori* – (1994) ECR I-3325 para. 22 seq.), the private party suffering loss from the nonimplementation of the directive may invoke the defaulting member state's government liability (see Section Ensuring Compliance with Community Law). Although the case law has eliminated some of the differences between the directive and the regulation, conspicuous differences remain. The regulation creates uniform law whose appearance is the same in all member states, while the directive provides for a harmony of solutions at best; but even after that harmonization, it is still difficult to assess the precise state of the law in other member states in the area at issue.

It is generally acknowledged, and has been affirmed on various occasions by the Court of Justice, that the law of the Union is a separate legal system distinct from both international law and the national laws of the member states. Ever since the leading case *van Gend & Loos* was decided in 1963, the Court has also stressed the need for the uniform application of Union law in all member states (case 26/62, (1963) ECR 1). Two consequences follow from this premise: Union law has to be interpreted autonomously, i.e., without reference to definitions established in national law; moreover, as recognized in *van Gend & Loos*, the law of the Union must be given direct effect and precedence over national law, insofar as its provisions are sufficiently clear and unambiguous. In the course of time the conditions for direct effect were watered down. At present, direct effect is the norm rather than the exception; it applies to many Treaty provisions, to regulations, and even to many directives (see above). By the doctrine of direct effect the Court of Justice has obliged the national courts to enforce Community law; a duty, which has been accepted over time by the national judiciaries.

Ensuring Compliance with Community Law

The institutions of both the Union and the member states must comply with the law of the Union. Acts adopted by the institutions of the Union are subject to legal review (cf arts. 263 and 265 TFEU). In the case of a violation of its laws committed by the Union or by its servants, the Union may incur liability under art. 340 para. 2 TFEU. With regard to the member states, the Treaty ensures their compliance with Union law in a much less comprehensive way. Under arts. 258 and 259 TFEU, the Commission and member states are entitled to bring a violation before the Court of Justice. In practice, only the Commission has made use of this right. The Treaty does not provide for a direct right of action of individuals who complain of a violation of Union law committed by a member state, nor does it establish the liability of member states for such violations. Both gaps have been filled by judge-made law. By the aforementioned doctrine of direct effect, the Court has enabled and instructed the national courts to disregard national provisions that violate the law of the Union. Private parties may therefore invoke the law of the Union in national courts, which can ask the Court of Justice for a preliminary ruling under art. 267 TFEU if they have doubts about the interpretation of the relevant provisions of Union law. In addition the Court of Justice has established the member state's liability for violations of Union law. Insofar as the respective member state has manifestly and gravely disregarded the legal limits of its political discretion, it has to compensate private individuals who have suffered loss as a consequence of that violation. This concerns, in particular, cases of a continuous breach of the obligation to implement a directive (cases C-46/93 and 48/93 – *Brasserie du Pêcheur v. Germany and R. v. Secretary for Transport, ex parte Factortame* – (1996) ECR I – 29; cases C-187 et al. – *Dillenkofer v. Germany* – (1996) ECR I – 4845).

Principles of the Internal Market

Among the various policies of the Union listed in art. 3 TEU, the establishment of the Common Market – later renamed the Internal Market – has always been of central significance. With regard to other policies, the Treaty either limits the activities of the Union to the 'support' of efforts made by the member states (e.g., with regard to health protection, education, industry, or culture, cf art. 6 TFEU), contains vague indications as to the direction of a Community policy (economic and social cohesion, research, transeuropean networks, consumer protection, cf art. 4 TFEU) or empowers the Community only to conduct

a policy in a given area without indicating any specific targets (agriculture, transport, environment, energy). In contrast to these policies, the establishment of a Common Market or Internal Market is not only an unequivocal objective stated in art. 3 para. 3 TEU, the basic principles of such a market are also spelled out in clear and operative rules throughout the Treaty. Thus, art. 26 para. 2 TFEU defines the Internal Market as "an area without internal frontiers in which the free movement of goods, persons, services and capital is ensured." These basic freedoms are guaranteed in further provisions of the Treaty which the Court of Justice has interpreted as producing direct effect. National provisions which subject certain markets and activities to regulations in the interest of consumers, of safety, of the environment, etc., are therefore regarded as restrictions of the basic Community freedoms and will be approved only if mandatory requirements of the public interest so command (case 120/78 – *Cassis de Dijon* – (1979) ECR 649 para. 8, 9). By elaborating in a long line of cases, both the basic rule of free movement and the exception in favor of national restrictions, the Court of Justice effectively paved the way for the deregulation of many markets in Europe in the 1980s and 1990s. While political and economic discussions on deregulation were often deadlocked, a single judgment of the Court of Justice would announce a new deal for further negotiations. The case law being inspired by a strong attitude against all kinds of discrimination on grounds of nationality (cf art. 18 TFEU), the Court has effectively opened national markets to competitors from other member states.

The basic freedoms are directed against restrictions imposed by states. Their implementation extends the scope of private liberties to engage in certain activities but they do not compel individuals and companies to actually do so. Market actors may also fear the intensification of competition and therefore try to maintain by private agreement the barriers to market access, which were previously ordered by national legislation. The risk of such anticompetitive agreements and practices had been foreseen by the founders of the Community, who therefore explicitly provided for the prohibition of anticompetitive agreements and of abuses of market dominance in arts. 101 and 102 TFEU. The enforcement of competition law, which is entrusted to the Commission and to national competition authorities, must be regarded as a complement of the basic freedoms: while the latter purport to open up markets by removing national restrictions, the former is meant to protect that competition against private restrictions.

While the basic freedoms have been implemented to a large extent, the opening up of internal markets is far from being a reality in many sectors. This is due to a great number of remaining and sometimes hidden obstacles. Thus, while nationality requirements for certain jobs have been abolished all over Europe, it is still lawful for member states to require a particular type of qualification, which, in the absence of a harmonization in the field of education, can hardly be acquired by foreigners in other member states; consequently, these jobs are still closed for foreign applicants. Another impediment to the opening up of internal markets is in the diversities relating to the legal framework of transactions, in particular in civil and commercial law; they deter many small traders from making use of their basic freedoms. While the Union is empowered to approximate the laws of the member states for the purposes of the internal market (cf art. 114 TFEU), it makes slow progress in that area.

The need for coordination of national economic policies was already considered a corollary of the common market in the early days of the European Economic Community (see art. 119 s. TFEU). It became even more conspicuous when the majority of the member states agreed upon monetary union in the Treaty of Maastricht and introduced the Euro as the common currency (art. 127 s. TFEU), thereby abandoning the role of exchange rate fluctuations as an arbitrator between the divergent economic policy orientations of member states. Tensions between the existence of the common currency administered by the European Central Bank and obvious deficits of the alignment of national economic policies have led to serious crises of the balance of payments and public debt in some member states and continue to be a major challenge to the stability of the Union.

Fundamental Rights

The EEC Treaty of 1958 did not contain a list of unalterable rights. While some fundamental rights of that type were guaranteed by single provisions scattered over the Treaty, such as prohibitions of discrimination or the basic freedoms, their scope was limited. It was therefore possible that secondary legislation could infringe private rights that were protected as fundamental rights granted by national constitutions. With respect to such situations, the German Constitutional Court indicated that it would subject the secondary legislation of the Union to the basic rights granted by the German constitution, so long as the Community had not developed a charter of basic rights of its own. A constitutional dispute between the Community and some member states appeared inevitable. In response, the European Court of Justice began to acknowledge the fundamental rights flowing from the constitutional traditions common to the member states and from the European Convention on Human Rights (UNTS vol. 213, p. 221) as an integral part of the general principles of law protected by the Court (case 11/70 – *Internationale Handelsgesellschaft* – (1970) ECR 1125 at 1134). It was only in December 2007 that the Treaty of Lisbon conferred binding effect on the Charter of Fundamental Rights of the European Union (cf art. 6 TEU). The charter can be expected to provide a basis for further judicial integration of the Union.

Abstract

European archaeology is the study of the material culture left by past inhabitants of the European continent over a time range extending back at least one and a half million years. Our predecessors were as mixed ethnically as they were culturally and made their homes in Europe's diverse microregions and microclimatic zones. They left a rich legacy of material traces and it is from these that archaeologists can reconstruct the complex patterns of their lives. The study of European archaeology had its beginnings during the Renaissance, when the classical world was rediscovered. But it was not until the end of the nineteenth century, when improved methods of classification, excavation, and relative chronology emerged, that archaeology became an academic discipline. By the twentieth century, European archaeology's major tenets had been established as had conflicting schools of archaeological thought. When the Iron Curtain fell in 1989, European archaeology experienced a new rupture. Terrain that was once impenetrable and colleagues and research that for decades had been unreachable suddenly became available. This exchange has both incited rich dialogue and stirred stimulating controversy. Spectacular recent finds such as the Iceman from the Italian Alps and technological advances such as the ability to analyze prehistoric DNA are revolutionizing archaeology revealing new insights into the past.

This article is divided into five parts, each of which outlines the major chronological and cultural shifts in European pre- and protohistory. Also included are major finds that have significantly altered or enriched knowledge of the past.

Europe's Origins – The Paleolithic and the Mesolithic

The early stages of human settlement in Europe took place against a background of severe fluctuations in climate and sea level that marked the Pleistocene 'Ice Age,' changes that probably impacted profoundly on demographic patterns and subsistence. The first European hominins may have belonged to the species known as *Homo erectus*, which originated in Africa but had dispersed into Southwest Asia 1.8 mya. Finds of simple stone tools indicate the presence of humans in southern Europe by about 1.5 mya. Fragmentary hominin fossils, thought to be over 1 million years old, have been found at the sites of Orce and Atapuerca in Spain and assigned to the species *Homo antecessor*. A new hominin species, *Homo heidelbergensis*, associated with more advanced stone tool technologies (both ultimately of African origin) was present in Europe 0.6 mya. This early period in European prehistory is known as the Lower Paleolithic. It was succeeded by the Middle Paleolithic, beginning around 300 000 years ago and marked by more advanced ('prepared core') stone flaking technologies. The emergence of prepared core technologies broadly coincided with the appearance of a new hominin species in Europe, *Homo neanderthalensis*. Unlike their predecessors, the Neanderthals buried their dead. Some burials appear to have been accompanied by grave goods, indicating that these hominins had some sort of belief system with notions of an afterlife. The Neanderthals hunted and scavenged, but they also ate fish, birds, and wild plant foods.

The Middle Paleolithic ended when the Neanderthals were rapidly replaced by the first modern humans (*Homo sapiens*) who had originated in Africa over 150 000 years ago and later dispersed into Asia and eventually Europe. *Homo sapiens*, whose physical appearance and cognitive abilities were similar to ours, were present in several parts of Europe 40 000 years ago. Their expansion into Europe marked the beginning of the Upper Paleolithic stage and was perhaps facilitated by a rapid warming of climate around 45 000 years ago. During this time, there were important advances in technology and a wider range of materials (including bone, antler, ivory, and shell) was used for manufacturing tools, weapons, and body ornaments. Cave paintings first appear in the Upper Paleolithic. The paintings mainly depict animals; however, abstract signs and patterns are also common. The sites of Altamira in northern Spain and Lascaux, Chauvet, and Cosquer in southern France offer particularly vivid examples. Remarkable are the carved female figurines depicted with exaggerated breasts, stomachs, buttocks, and thighs. They have been found all over Europe; among the best-known examples are those from Willendorf in Austria and Dolní Věstonice in the Czech Republic.

The Mesolithic marks a continuation of the hunter-gatherer way of life into the Holocene, when interglacial conditions returned to Europe once more. The time range of the Mesolithic varies from region to region; it began around 10 000 BC and came to an end with the arrival of farming, which took several millennia to spread across Europe. With the rapid warming of climate at the end of the Pleistocene, the tundra and steppe that had covered much of Europe and were home to vast herds of wild horse, reindeer, and bison were replaced by forests that supported much smaller numbers of animals like red deer and wild boar, which in turn supported fewer people. It is hardly surprising, therefore, that many Mesolithic communities relied on fishing for their subsistence, with the largest concentrations of sites found along sea coasts and the banks of large lakes and rivers. The dietary emphasis on aquatic resources and the existence of quite large cemeteries like those at Skateholm in southern Sweden, Zvejnieki on Lake Lubāns in Latvia, and sites along the Danube and Dniepr rivers in southeastern Europe, suggest that Mesolithic fishing communities often lived in permanent or semipermanent settlements. But Mesolithic people were not just fishers; they also hunted land game (with

bows and arrows, spears, and traps) and gathered wild plants for food, medicinal, and other purposes. Most groups also kept dogs. In some regions, including much of Scandinavia and the eastern Baltic, where the growing season for crops and pasture is short, a fishing-hunting-gathering economy continued long after farming was introduced to other parts of Europe.

The Emergence of Farming and Social Complexity: The Neolithic and the Copper Age

The Neolithic is often identified by the appearance of domestic animals and crops. This huge change revolutionized European history. It is accompanied by an increase in the size and complexity of settlements as well as the use of pottery and polished stone tools, and in some regions, the erection of elaborate monuments. During the Neolithic, people began to view the world in a whole new way. Farming revolutionized ways of life and subsistence. The human diet shifted from an almost total dependence on wild animals to a diet based primarily on cereals and domesticated animals. Sedentary life had demographic consequences and as populations increased, society became more complex and stratified.

Early Neolithic communities came to Europe from the Near East and Anatolia around 7000 BC, and first settled in the southeastern part of the continent in Greece and the Balkans. As in Anatolia, subsistence was based on emmer, wheat, sheep, goats, pigs, and cattle. Farmers inhabited open settlements and lived in freestanding, rectangular houses. Some settlements were inhabited for long periods and the constant building and rebuilding led to the emergence of large settlement mounds (tells). From these southeastern settlements, Neolithic communities dispersed across Europe. The movement went in two general directions: to the north and northwest and to the west along the Mediterranean coast. The process of colonization varied tremendously, as did the adoption of domesticates. In southern Scandinavia and the British Isles, for example, it occurred around 4000 BC, while in central Germany, it occurred about 1300 years earlier. The western route of Neolithic colonization led along the Mediterranean coast to southern Iberia and southern France, both of which were colonized around 5500 BC. These routes have been identified closely with the spread of Impressed Ware Pottery. From the Mediterranean, domestication and farming moved northward along the Atlantic Coast into the Parisian Basin. Here, the southern route met the northern route. This route, which followed the Danube through central Europe, is associated with Linear Pottery and showed advances in the use of longhouses, incised decorated pottery, and the shoe-last adze for clearing forests. By 5300 BC, the Neolithization of continental Europe was complete. The most significant pottery emerged from the Chasseen culture in France, the Michelsberg culture between the Rhine delta and the Alps, and the Trichterbecher culture in northern and eastern Europe. Along the Atlantic Coast, from Portugal in the south, the Orkney Isles and Scandinavia in the north, and Poland in the east, large megaliths in the form of standing stones, stone circles, henges, and cursus monuments have been found. During the fifth millennium BC, copper metallurgy was introduced into southeastern Europe, specifically in the Balkans and the Carpathian Basin. This period, which lasted from 4500 to 2500 BC, is hence known as the Copper Age.

Economic changes such as the introduction of the wheel and plow, wool production, and the increased use of animals for specialized tasks occurred. Together, this is known as the Secondary Product Revolution. At this time, more emphasis was placed on creating cemeteries than on erecting domestic structures. Cemeteries were a means of establishing group identity and instilling a sense of belonging. A spectacular example of this is in Varna on the Black Sea coast of Bulgaria. Here, individual graves featured sophisticated gold and copper work. By 3000 BC, the explosion of new innovations ruptured traditional lifestyles across the continent and change occurred rapidly. As wealth became portable, emphasis shifted from places to people and from collective to personal possessions. A symbol of this change is Corded Ware pottery, which is decorated with impressed cords. Such pottery has been found in male graves located under circular mounds across northern and central Europe.

In addition to the pottery, men were found in single graves accompanied by stone battle-axes. This has both been interpreted as a sign of the importance of fighting and drinking and of individualization within a stratified society. A second type of pottery, handless drinking-cups known as Bell-Beakers, appeared concurrently and slightly later in the expansive area from Scotland to Sicily and Spain to central Europe. Graves were flat graves and in some regions also individual round mounds and, along with Bell-Beakers, contained daggers and archery equipment such as triangular barbed-flint arrowheads and wrist guards of fine stone. The vast distribution of the Bell-Beakers across temperate Europe and the Mediterranean indicates an increasingly mobile lifestyle that arrived just as traditional social structures disintegrated.

The Emergence of Elites: The Bronze Age

During the second millennium BC, bronze became the universal medium of ordinary objects and also of prestige. Horses and wheeled vehicles, textiles, amber necklaces, and metal dress-pins for clipping wool clothing emerged as visible signs of wealth. Trade in bronze expanded and bronze became popular for manufacturing weapons, ornaments, and tools. Most importantly, metallurgy shifted as copper became regularly alloyed and tin began to replace arsenic. Although copper is relatively rare as a naturally occurring material, tin is even rarer and the creation and circulation of bronze objects depended on regular supplies of both. This led to the rise of leading centers of metalwork, each of which made technical advances in bronze casting that were widely diffused and adopted. As techniques of war changed, so did the types of weapons used. New bronze weapons and designs spread across the continent.

In central Europe, in a region known as the Carpathian Basin, where the Únětice culture flourished, large hoards of bronze objects and magnificent burial mounds filled with gold and bronze objects have been uncovered. The influence of these communities stretched from Denmark to Italy to Greece, and to some degree, the British Isles. In the western Mediterranean, similar developments around 2200 BC spawned the establishment of new centers along the coast of the Iberian Peninsula. Here, hilltop settlements containing rectangular

houses and streets were surrounded by stone walls. These settlements lasted throughout the second millennium and are called El Agrar. The proximity of urban cultures in the eastern Mediterranean also provided alternative centers of trade and exposure to novel eating and drinking habits, clothing, furniture, means of transport, prestige ornaments, and weaponry.

Demand for bronze by the populations of the North Pontic steppes spurred trade and soon communication and exchange networks were established. North of the Caspian Sea, new grave architecture that included timber-built underground chambers known as Timber Grave culture was found. Eastward, the closely related Andronovo culture perfected the use of horses and created a horse-driven chariot complete with a bridle-bit with spiked cheek pieces made of antler. At the timber grave cemetery of Sintashta in the southern Urals, shaft graves similar to those of Mycenae were found containing wheeled chariots and horses.

When the palatial societies of the eastern Mediterranean collapsed after 1300 BC, dramatic changes swept across Europe. This period is known as the late Bronze Age and is characterized by hill-forts, flat cemeteries, scrap hoards, and votive finds from rivers. The most striking sign of the changes is the almost-universal shift from burying the dead in graves to cremating them and putting their ashes in pits or funerary urns. The period lasts until *c.*800 BC and has been named the 'Urnfield Period.' It is a transitory time, a phase in between the Bronze Age and the Iron Age, in which economic, social, military, and religious changes that are of pivotal importance in the formation of historic Europe occurred. For the first time, swords, spearheads, armor, safety pins, and certain ornaments from central and northern Europe appeared in the Mediterranean. Hilltop forts and stockades on lower ground became popular around 1100 BC and lasted until *c.*550 BC. At Biskupin, near Bydgoszcz in Poland, a fortified settlement island with 13 parallel rows of houses divided by roads and encircled by a rampart were excavated. The layout resonates communal order and indicates the presence of a coercive power. Throughout the period, exchange networks allowed goods to travel over vast distances and for the first time salt from the Austrian Alps and other places emerged as a valuable trade commodity. Hallstatt, the richest cemetery of the period, sits on top of a salt mine. Spiritual life also took on great importance and the bird became a beloved symbol. Figurines in the shape of birds have been found, as have numerous pots, cauldrons, and cult wagons with bird applications. Numerous rock carvings with engravings of humans, animals, boats, and a variety of symbols were found in Sweden (Tanum), the Alps at Val Camonica, north of Brescia, and on Monte Bego near Bordighera. The abundance of swords, daggers, spearheads, arrowheads, and armor found indicates the importance of war and the extensive choices available to the warrior.

From Chieftain to 'State' Organization in Celtic Europe: The Iron Age

By 600 BC, iron became the standard material for tools and weapons, while bronze was used for high-quality art products. The explosion of trading ports around the Mediterranean provided a strong incentive for European development. Mediterranean goods were sought avidly and the most valuable ones were acquired by the wealthy as proof of their exalted status. The valleys of the Rhone and Saône provided easy access to the region from Burgundy to southern Germany. This west Hallstatt zone was pivotal as it spanned the upper courses of the Seine, Saône, Rhine, and Danube rivers and directly linked the continent north of the Alps. Greek-led trade intensified through the colony of Massalia in the sixth century and the elite in this northern zone controlled trade of exotic Mediterranean products, including prestige equipment for wine-drinking rituals of the Greek symposium. Large valuables, such as the human-sized bronze crater from Vix, were imported and were exchanged for local products and slaves. The native elite maintained full control of these exchanges and likely held lavish feasts and gift exchanges among important chieftains, including the famous chief from Hochdorf. At graves, social prestige was demonstrated by the inclusion of costly sets of wine-drinking equipment and other exotic gear with the dead. Funerary rituals took place in large-scale religious structures surrounding burial mounds. At Glauberg in Hessen, a 1-km-long ceremonial path leading to a grave from the early La Tène period was recently discovered. Hilltops also emerged as prime locations for defended residences for the nobility. At Mount Lassois in Burgundy and at the Heuneburg in Germany, huge quantities of Mediterranean luxury goods were found. The Heuneburg was surrounded by a mud-brick wall built on dry stone footings with forward-projecting rectangular bastions. This technique, common enough in the Greek world, was totally alien to temperate Europe, and is a striking example of how avidly the European elite adopted Mediterranean achievements, even when they were impractical for the climate. In the east, in Slovenia, a second group of less-wealthy communities known as the east Hallstatt zone arose from the eighth to the fifth centuries. They were characterized by fortified settlements such as Magdalenska Gora, Vače, and Stična and large cemeteries with aristocratic graves furnished with sheet bronze body armor and decorated situlae.

The rise of a new warrior elite and the drying up of the market for luxury goods in the early fifth century destabilized the east and west Hallstatt systems and by the middle of the fifth century caused their demise. A new, northern elite arose and relied on native craftsmen to produce luxury goods. Numerous late fifth-century elite tombs have been found containing locally made masterpieces of Celtic-style art. Schools of creative metalworkers emerged during this period and their work led to the creation of the first truly Pan-European art style, known as Celtic or La Tène art. A rapid population increase, evident in the growth in the number of cemeteries, ensued and shook the social equilibrium. Over time, the system collapsed and resulted in a widespread migration. Late fifth- and early fourth century cemeteries, which extend south into the Po Valley and east along the Danube into Hungary, trace the path of this migration. Some early groups also crossed the great Hungarian plains and settled in Transylvania. In the Marne-Moselle region, elite burials continued at Somme-Bionne, Reinheim, and Waldalgesheim. But overall, the number of cemeteries decreased, indicating migration. In the tombs, young men were usually found accompanied by spears, swords, and shields. Wealthier men had bronze helmets and some possessed two-wheeled chariots. It is these warriors, called 'Gauls' or 'Celts,' who, in tens of thousands, made their way across Europe seeking new lands to

conquer and settlements to plunder. The Celtic migrations between 450 and 200 BC can be traced archaeologically across Europe through the La Tène culture, which is characterized by art depicting mobility, upheaval, and turbulence.

The northern limit of La Tène culture lay at the mouth of the Rhine and across southern Germany and northern Italy to the Carpathians. Further east, the Celts were well established in the lower Danube region. In the early fourth century, they began moving eastward into Transylvania and in the third century they pushed into southern Thrace and Greece. In the northeast, Celtic groups crossed the Prut and Dnestr, exploiting the power vacuum left by the decline of the Scythians. One of the few surviving pieces of silver made during the disrupted Celtic period is the Gundestrup cauldron found in Jutland. The puzzle of this elaborate cauldron encapsulates the complexity of these migrations. The techniques used to make it are typically Augustian Thracian. Some of the figures on it such as a warrior wearing a bird-crested helmet look Celtic, while other motifs are reminiscent of steppe shamanism. The cauldron was probably carried north as booty by raiding Germans.

Center and Periphery: Barbarian Europe and the Roman Empire

For Rome, the Rhine River marked an ethnic divide between the Celts to the south and the Germans to the north. In reality, tribes on both sides of the river had integrated to such a degree that few ethnic differences existed. Wealth derived from constant access to particularly fertile land and did not build up in the hands of any single group. Status could, however, be acquired by acts of bravery and leadership in raids. Power at this time lay with the elite and was measured by entourage and the ability to bestow patronage. The elites formed the tribal council. Caesar overran Gaul fairly easily because the Gauls were a settled people with a well-developed agricultural base and tribes centrally located on permanent defended settlements known as oppida. Oppida were the first urban centers in temperate Europe and have been found from France to Serbia. At Manching in southern Germany, the settlement was densely built up with regularly laid out timber buildings aligned along straight, ordered streets. A wide range of craft skills were practiced and coins were minted. Commodities such as wheel-turned pottery, glass beads, bracelets, and ironwork of every kind were done on an industrial scale. In oppida like Bibracte, cargoes of wine amphorae were exchanged with the local aristocracy for slaves and other commodities. This stability made Gaulish society soft and vulnerable. Germans were the opposite. Mobility and warfare were central to their lives and they had few southern luxuries. Since they had no oppida to protect, they could simply retreat and disappear. The Roman Empire desperately needed a continuous supply of raw materials and manpower. As its frontiers continued to expand, valuable metals and other commodities arrived. Rome's greatest dependence lay in its need for slaves to keep the Roman system working. The scale of the slave trade was enormous. Judging from the distribution maps of artifacts in Free Germania, Romans traded coins extensively, but also traded sets of metal vessels used for wine-drinking rituals, buckets, situlae, and jugs. In this zone, a number of rich burial sites known as Lübsow were found. The graves contained extraordinary luxury goods, indicating that the dead were members of the elite, who, by virtue of their rank, were able to acquire a set of the most costly Roman items. Such local elite served as middle men between the Roman world and the Baltic region. This system of socio-economic zones continued until the middle of the second century AD, when population expansion, social instability, and folk movements in central Europe built up and pressured tribes along the frontier. They then threatened the stability of the Empire. The territory occupied by the warrior burials coincides with the region from which the Burgundians and Vandals are thought to have emerged. The first recorded indications of the growing problem came in AD 162 when a frontier tribe, the Chatti, attempted to migrate south into Roman territory. A few years later, the Longobardi and Marcomanni crossed the Danube into Transdanubian Hungary. This was followed by even more massive movements by other tribes. These events, and the Marcomannic War fought by Rome between AD 166 and 180, mark the beginning of a wave of migrations which within three centuries destroyed the Empire and laid the groundwork for the formation of medieval Europe.

Abstract

Most concepts of Europe as a unitary imagined community are characterized by a bipolar scheme in which Europe is opposed to 'anti-Europe.' However, it is misleading to think of Europe as a united civilization or as a sum of cultural areas. Europe is considered as a system of structurally and culturally diverse historical regions.

The article also deals with the relevance of European nation-states in the past and in the framework of the present globalization processes. It shows how Europe experiences a difficult, tense, and contradictory transition from a Europe of the national communities to a postnational Europe.

The Term 'Europe'

In ancient Greece, the term 'Europe' evoked legendary or divine characters from the mythological universe rather than a geographic site.

The notion of Europe took on a more political and sociocultural connotation during the Carolingian period (seventh to eighth century). According to a medieval anonymous chronicle, the soldiers led by Charles Martel, who fought victoriously against the Arabs at Poitiers (732), were 'European.' At this time, the notion of Europe was assimilated with the Frankish Kingdom, and the idea of Europe as a political-spiritual entity developed along with the expansion of Arab-Muslim settlements north of the Strait of Gibraltar.

One of the recurrent themes of various subsequent concepts of Europe as an 'imagined community' (Anderson, 1983) can be noticed *in statu nascendi* from the latter observation. It is characterized almost without exception by a scheme in which the notion of Europe appears together with another contrasting term. In most cases, it is a dichotomy or bipolarity, rather than a comparison between what Europe is reckoned to be and what is supposedly its opposite. This 'European self-awareness,' as Denis de Rougemont (1990) calls it, becomes even more tangible at the time of geographical discoveries and the first colonial conquests.

From an anthropological point of view, Europe discovers itself by discovering and conquering the rest of the world. Between Europe and anti-Europe, which from time to time could be the Arab-Muslim culture or Asia, Africa, or the Orient, there is a reflective relationship in which the former identifies its basic traits through a presumed diametrical difference with the latter. Balthazar Gracian (1601–58) coined the famous phrase "Europe is the admirable face of the world." Following the same train of thought, the *Grand Dictionnaire historique de Louis de Moreri* (published in 1674) illustrates the European traits that have allowed Europeans to overpower the people of other continents. It is quite surprising to read statements in this publication that seem to foretell the stereotypes of German Völkerpsychologie as well as American studies on modal personality and national character. Similar arguments were expressed more briefly and clearly by Carl von Linné (1707–78); the Swedish naturalist describes Homo Europaeus as subtle and creative while Asians are melancholic and miserly and Africans are sly and lazy.

During the *ère des philosophes*, almost all of the eighteenth century's great thinkers – Montesquieu, Voltaire, Jean-Jacques Rousseau, Ferdinando Galiani, Melchior-Gaspar de Jovellanos, Antoine de Condorcet, Edward Gibbon, Edmund Burke – pondered over the 'European peculiarity.' Their dissertations share a common denominator: a scheme, usually bipolar, in which at least one other term of comparison appears besides Europe. Thus the main question for most of these authors is why European nations are the only ones that have reached such levels of civilization, while the other societies are still savage, primitive, or barbarian. Leaving aside the answers, almost all eighteenth-century texts on Europe draw either implicit or explicit parallels and hierarchies between 'we' and 'they,' between Europe and anti-Europe.

During the nineteenth century, the notion of Europe had an increasingly hegemonic connotation. The century was characterized by a bold optimism that turned out to be an awful self-deception. In historical terms, European elites had surprisingly underestimated the changes that had been going on beyond their continent. For example, they had overlooked the dynamic and intensive socioeconomic and cultural relations involving various Asian societies on the Indian Ocean's rim well before the arrival of European colonial empires; the formation of pre-Columbian empires in Mexico and Peru; the Japanese development model spurred by the emperor Mutsuhito, better known as Meiji Tenno (1852–1912), who had opened his country to foreign commerce; and even the American 'great transformation.' Throughout this century and to some extent the next one, Europeans would obstinately emphasize their superiority, as Eric Wolf has aptly highlighted, by stubbornly disowning the history of others (Wolf, 1982).

It is no surprise that the term 'Europe' was being increasingly used as a synonym with 'civilization' and 'progress' (Schmitt, 1974). From a European point of view, the Old Continent was the only one that could establish a 'civilizing movement' to 'break through the darkness that enfolds whole populations' as Leopold II (1835–1909), King of the Belgians, stated in a solemn speech in 1876. For this typical representative of the time, European colonial expansion in the heart of the anti-Europe of that moment, namely Africa, was 'a crusade worthy of this century of progress.'

Nineteenth-century certainties were radically curtailed by the First World War, which the German philosopher Karl Löwith (1897–1973) keenly called 'the first European civil war' (Löwith, 1990); by the critical analysis of the nationalistic and totalitarian frenzy between the two World Wars; by Second World War traumas; and finally by the melancholic awareness of crumbling colonial empires. Europe as a notion became less triumphalist and much more defensive. After 1945, Europe was perceived as suffering from a chronic economic, cultural, and above all political and military fragility. This intrinsic deficiency could be checked only by a strong synergy between all the continent's components sharing the same fate. In this respect, the French sociologist Edgar Morin (1987) has fittingly spoken about Europe as a *Schicksalsgemeinschaft*, a term first used by the Austro-Marxist theorist Otto Bauer (1881–1938). From a sociological point of view, the European fragility concept implies a menace coming from external hostile forces. Each community, especially if it is a *Schicksalsgemeinschaft*, is strengthened or crystallized if under pressure from an actual or presumed enemy. The part of Europe that after the Second World War was not under Soviet control always reverted to the anti-Europe theme to emphasize who the menace was. From 1945 until 1989, while Europe was establishing its first joint institutions, the leading anti-Europe menace was the Soviet and communist sphere.

The fall of the Berlin Wall (1989) and the subsequent disintegration of the opposing blocs coincided with the birth of a new European institution, the European Union (EU). A fragile and 'menaced' Europe was still a common perception in the Old Continent despite this new highly specialized and official legal apparatus. Behind this defensive attitude, some authoritative, although overly severe, 'Euro-skeptic' critics detected the danger of the creation of a European fortress that wishes only to defend an acquired economic standing threatened by supposed external menaces. At the end of the twentieth century, the bipolarity between Europe and anti-Europe still existed. Now anti-Europe is mainly the planet's boundless south, with its migratory waves toward the Old Continent, its high demographic rates, and political–religious conflicts.

What Europe Is Not: Some Misleading and Dangerous Ideas

During the twentieth century, notions of Europe with powerful ideological implications have occasionally been spread; yet they can hardly endure a historical, sociological, and anthropological analysis. The idea of European civilization as a monolithic entity was most popular and politically relevant. European civilization was seen as the bulwark of Christianity. This concept of Europe was an ideological backbone of antidemocratic political movements. Though admittedly in conflict with Christian doctrine and ecclesiastic institutions in many aspects, German Nazism and Italian Fascism envisioned themselves as the upholders of European civilization and strenuous paladins of Christianity, particularly against Soviet Bolshevism, which was stigmatized as Asian and hence alien to Europe. Other régimes with similar ideological backgrounds, such as authoritarian and dictatorial governments and movements in Central and East European countries as well as Francoism in Spain and Salazarism in Portugal, resorted to analogous ideas.

Europe as a united civilization embodied in the Christian Occident is an idea that can still be found in present-day European extreme rightists, such as the French Front National and neo-Nazi and neofascist fringes in Germany, Austria, and Italy. These movements resort to similar concepts to assert their hostility toward immigration, especially from Islamic and/or non-European countries. It is a dangerous idea because it implies the pursuit of cultural, denominational, and maybe even ethnic homogeneity based upon the 'exclusion strategy' and the 'purity myth,' which caused so many of Europe's tragedies during the twentieth century. This vision of Europe is misleading since it is far-removed from the continent's past and present social realities.

Europe: A System of Historical Regions

The German philosopher Ernst Bloch (1885–1977) advises us not to turn a highly differentiated social entity like Europe into a sum of 'cultural areas' because this would turn "History … into a circus [with] three or more [separate] rings" (Bloch, 1985). Europe must be considered a system of strictly (inter)dependent, yet structurally diverse historical regions. Hungarian historian Jenö Szücs (1983) was the first one to apply a strictly scientific method to the problem of Europe's internal frontiers, and thereby to the question of its historical divisions, and consequently to Europe's sociostructural differences.

Szücs stresses that from the early Middle Ages, Europe began to differentiate socioeconomically, giving rise to two different poles: *Europa occidentalis* and *Europa orientalis*. The boundary would be an ideal line running from the Elbe River (a socioeconomic boundary between western and eastern Germany) to the Leitha River (for many centuries a pervious frontier between Austria and Hungary). A second economic and sociostructural division, which includes all societies involved in the Great Schism (1054), came to pass between the eleventh and fourteenth centuries. Thus, there are three historical regions with very diverse socioeconomic, political, and cultural characteristics. The first includes the territory from the Atlantic to the Elbe–Leitha ideal line, corresponding more or less with Carolingian Europe, today believed to be the quintessence of Western Europe. The central historical region east of the Elbe–Leitha line but west of the eastern and southern borders of the original kingdoms of Hungary and Poland (Grand Duchy of Lithuania included), approximately overlaps what is known today as mid-Eastern Europe, also called *Mitteleuropa*. Everything east of the Baltic–Black Sea line or south of the Carpathians is Eastern Europe proper.

Szücs' arguments are relevant for the social sciences because they reveal how processes dating back to a remote past have created lasting economic, sociostructural, and cultural differences in Europe; however, his hypothesis of at least three historical regions must be broadened and further examined. For this purpose Immanuel Wallerstein's analysis of Europe incorporated in a 'world-system,' yet divided into a 'core' and 'peripheries' (Wallerstein, 1974), is well suited. A new system to organize and manage the economy emerged and spread

between 1450 and 1640. Max Weber labeled this new system rational capitalism. According to Wallerstein (1974), as well as to French historian Fernand Braudel (1979) among others, expansionist movements are inherent to this new model of economic and social behavior. The capitalist economy's worldwide expansion implies new relationships between economic partners, that is, societies, states, regions, towns, and so forth. These new relationships entail a new international division of labor that will permeate social structures and cultural models of all societies involved.

The international division of labor within the world-system is also based on a systematic separation between core and peripheries. Europe at first, and then the whole world, came to be divided into a number of regions. Some of these underwent a historical acceleration, quickly modernizing most of their socioeconomic structure, while others suffered centuries of socioeconomic stagnation if not growing impoverishment. The following classification highlights the roles of Europe's historical regions within the new international division of labor.

Northwestern Europe

The first core of the world-system developed in this region. Steady decline of the feudal system, early establishment of an extended net of self-governing towns (*freie Reichstädte*, *comuni*, etc.), striking capital accumulation followed by important technological changes culminating in the industrial revolution, rise of strong territorial states with more culturally homogeneous populations, colonial expansion outside Europe: these are only some of the most evident processes marking the socioeconomic and cultural structure of this historical region. From the onset, it included southern England, France, Flanders, Holland, and the westernmost part of Germany. Northern Spain and Northern Italy, other areas of Germany, and most of Switzerland, Austria, Bohemia, and Scandinavia, joined the core in subsequent periods.

Mediterranean Europe

This historical region, for centuries the continent's socioeconomic and cultural hub, was turned into a vast periphery by the new international division of labor. It provided the core with foodstuffs and raw materials for the growing textile industry. From a socioeconomic point of view, the area comprising Portugal, Spain, and Italy was ruled by a system of wheat monoculture and/or stock farming with an absentee owner aristocracy. The vast properties were administrated by large tenants who would sublease to smaller ones, who in turn would sublease to the smallest peasants. This long renting chain led to a devastating fragmentation. Too many people without a productive activity lived exclusively off the land and backs of those who actually tilled it.

Even though the banking system, rational capitalism's pillar, was developed in Renaissance Italy, and the two Iberian states were the first ones to rely on imperial colonies, Mediterranean Europe's structure was rooted in agrarian societies and economies from the sixteenth century up to most of the twentieth century. The rising bourgeoisie of this historical region did not play a specific role, nor did it have its own specific economic behavior. Its ideal was to imitate the aristocracy. This matched the economic and social behavior of categories of tenants such as the *señoritos* in Andalusia, La Mancha, and Extremadura, or the *gabelloti* and *galantuomini* in Sicily and southern Italy, who were inclined to a passive existence on the principle of 'dignified idleness.'

Central–Eastern Europe

This historical region, with few exceptions, lies between the two ideal boundaries traced by Szücs. It is Europe's second vast periphery and has been one of the core's major suppliers of foodstuffs. The typical socioeconomic scenery of Europe's second periphery is in western and eastern Prussia, the Baltic countries, the Hungarian plain, and the Romanian Danube plain, together with Poland's so-called eastern territories (most of which were lost after the Second World War). In these boundless areas were the landed estates of Central–Eastern Europe's aristocracy: important Polish and Hungarian noble families, Baltic overlords of Germanic ancestry, and Romanian boyars. The institution of serfdom was the rule in these estates nearly up to the end of the nineteenth century. In fact, rather than being abolished, serfdom relationships were revived in what historians call the 'second serfdom.' Great landowners introduced new farming methods in order to increase crops, mainly cereals, causing harsher labor and life circumstances for the peasants. Central–Eastern Europe's second serfdom was also accompanied by the formation of new groups of great landowners with a strong corporate spirit and staunch political and socioeconomic ambitions, such as the Prussian *Junker*, Polish *Szlachta*, and Hungarian gentry.

Southeastern Europe

This historical region mainly includes the Balkans (except Romania). The Ottoman Empire that dominated it for almost 500 years became a part of the world-system only during the eighteenth century, that is, during its manifest decadence. However, even under the Ottoman domination the Balkans was a poor periphery on the precarious border between the Ottoman and Austro-Hungarian empires. Therefore, the circumstances of this historical region should not be compared to other more flourishing socioeconomic areas of the Ottoman Empire, such as parts of Syria or Egypt. To make matters worse, in the Balkans there was a degeneration of the patrimonial system based on 'tax-farming.' The Balkans' fate within the world-system was to become a 'periphery of the periphery.'

Eastern Europe

Europe's third historical region, according to Szücs' classification, comprises mainly Russian territory west of the Urals with the exception of the areas south of the Carpathians. During its first centuries, this enormous country was an 'external area' as regards the world-system, with a distinctive socioeconomic system. A communitarian land property regime and a peculiar patrimonialism by which an imperial official 'arrogated' property administrated on behalf of the czar were the socioeconomic structure's cornerstone. Historians compared the situation engendered by such a structural peculiarity, which lasted up to the Russian Revolution (1917), to a 'bog of misery'

(Riasanovsky, 1984). However, Eastern Europe's gradual integration in the world-system, beginning in the eighteenth century, remained incomplete. Russia continued to be a European external area and never became a real periphery or a core-state as other historical regions already described.

Historical Regions and Present Socioeconomic Gaps

The establishment of the world-system and the growth of a new international division of labor, which have molded the European core and peripheries, are the primary components of an epochal historical change whose socioeconomic and cultural consequences are visible to this day.

The gaps that appeared between Europe's historical regions during the formation of the world-system are still plain to see. The North–South gap mirrors past historical sociostructural and economic differences between the core and the Mediterranean periphery. To date, even the integration of these two historical regions within the EU has not eliminated the gap. The enlargement of the EU to the east is a problematic issue due to West–East discrepancies (and not only to 50 years of socialism) that embody old boundaries between the European nucleus and the central–eastern periphery. The Balkan situation, which is characterized by a feeble industrialization and an incomplete modernization, is due to the fact that for centuries this area was a periphery of the periphery. Finally, present-day Russia, with its distinct development model torn between capitalistic models and (pre)Socialist communitarist revivals, is adhering to its typical tradition of lingering on the borders of the world-system. The core-periphery gaps are detectable not only interregionally but also within the states. In fact, states that straddle historical regions have strongly dualistic societies, economies, and cultures. For example, Italy is divided into north and south; Spain has discrepancies between Catalonia and Spanish Basque Country on the one hand and the rest of the country on the other; in former Czechoslovakia there were differences between Bohemia and Slovakia; in former Yugoslavia, Slovenia and Croatia were more connected to the core while Serbia, Bosnia, and Macedonia belonged to the southeast periphery.

At the end of the twentieth century and in the early twenty-first century, the structural gap between core and peripheries was held to have been overcome thanks to the creation of the EU, to its various socioeconomic reallocative mechanisms, and especially to the introduction of a single currency. The current government debt crisis of the Mediterranean area countries (Portugal, Italy, Greece, and Spain), the severe economic problems in East and Southeast Europe's former communist countries (Latvia, Lithuania, Hungary, Slovakia, Romania, and Bulgaria), and the hegemonic aims and stances of some of Europe's northwestern nations (Germany in particular) are evidence that asymmetrical and dependency relations between core and peripheries are definitely not over.

Perceived Gaps: Core and Peripheral Identities

Core–periphery gaps go beyond structural data. They are also 'lived,' and therefore perceived and constructed realities. In fact, in the core there is a feeling of belonging dominated by the concept of techno-economic and social progress, of human perfectibility, and, based on the values of enlightened rationalism, of secularized and individualized societies, the spirit of capitalism, and so forth. Max Weber would have described such identities as 'disenchanted' ones. Maybe the most fitting description of this type of identity is precisely the one supplied by Max Weber in his model on Occidental uniqueness (Weber, 1986), which, despite what Max Weber intended to prove, was used to validate European superiority and the core's hegemonic aims on the peripheries.

In European peripheries instead, especially among the intellectual elites, there is an awareness of the marginality if not the backwardness of one's country or its historical region. However, there is also a strong belief that one's nation or people has outstanding excellence and virtues. Peripheral elites have been coping with the discrepancy between their nation's perceived socioeconomic inferiority and its presumed spiritual and moral superiority even at the brink of the formation of their respective nation-states. European peripheries' ruling-class interpretation of this apparent contradiction has been remarkably ambivalent as regards to relationships with the core as a socioeconomic and cultural complex. Quoting Reinhard Bendix's terminology, the core is looked upon as a 'reference society,' with whom there is both an 'identification' and a 'distinction' relationship (Bendix, 1978). An emulation of the core is encouraged, while dissociation is maintained as well. Over the past 150 years, almost every European periphery has undergone major modernization processes emulating the core, which affected all aspects of society. However, these processes were accompanied by archaistic countertrends (agrarian populist movements, nationalisms, etc.) that instead glorified what was deemed as the past, tradition, culture, and identity of one's group. A modernization drive and a nativistic revival were both at work.

A modernization drive basically means a Europeanization, particularly of politics (establishment of parliamentary institutions and legal systems), economy (industrialization), culture (more theaters, art museums, avant-garde arts, etc.), and even everyday life (new habits, conventions, and ephemeral fads from the capitals of 'reference societies' – Paris, Vienna, or Berlin). Nativistic revival means stressing one's distinguishing difference from the core and revitalizing imagined social institutions, guardians, and bearers of primordial virtues, such as the village, rural community, medieval municipality, or guilds.

Europe and the Sociocultural Order of Nation-States

Since the nineteenth century, capitalist economy's expansion in world-system Europe has been accompanied by a proliferation of nation-states that were established (except in the United Kingdom) through a combination or a separate use of two main models first conceived in France and Germany (Brubaker, 1992). Notwithstanding some differences, both concepts are based on the doctrine by which each nation is entitled to its own territorial state and each state must include only one nation.

Because of this ideal, the last two centuries have been marked by repeated efforts to make single national territories more and more ethnically and culturally homogeneous. Already from the twelfth to the seventeenth centuries, Western

Europe was overrun by several homogenization waves in the shape of religious conflicts and persecutions. Even in the more culturally homogeneous nation-states of Western Europe such as France, however, assimilation processes continued to the end of the nineteenth century (Weber, 1976). In Central and Eastern Europe instead, where the doctrine was applied only after the downfall of the multicultural empires, the processes of ethnocultural recomposition aimed at 'ethnic purity' have been implemented only during the nineteenth and twentieth centuries through a series of boundary revisions, forced assimilations, expulsions, aimed and planned immigrations, deportations, ethnic wars, and genocide.

Four main periods can be identified in the various processes of ethnic separation that over the last two centuries concerned the European nation-states, especially in the central and eastern parts of the continent. The first period occurred predominantly in the Balkans, immediately after the creation of the first nation-states in the nineteenth century. Vast population groups of Turkish origin or just of Islamic faith were forced to leave the region. As administrators of the Ottoman Empire, some did indeed represent the hated occupiers, but members of social strata that had little in common with the ruling class were also expelled. During the great 'Crisis in the Orient,' which led to the bloody Russian–Turkish war, between 1875 and 1878, a million and a half people were repatriated.

The second virulent phase took place between 1913 and 1925. It was characterized by the forced transfer of whole minority groups, yet it was internationally recognized and guaranteed. In diplomatic parlance, it was euphemistically termed 'population exchange.' Substantial groups of Albanians from Kosovo and western Macedonia were transferred to Turkey after the Balkan Wars (1913) mainly because of their religion. Particularly after the creation of the kingdom of Yugoslavia, the Islamic populations were replaced with Serbian, Montenegrin, Croatian, and Slovenian people. The 'population exchange' between Greece and Turkey was even more dramatic. The Treaty of Lausanne in 1923 ratified a series of reciprocal expulsions and hasty repatriations caused by the Greek military catastrophe during the campaign in Asia Minor. After the defeat, Greece was overrun by refugees from the coasts of western Anatolia, plus the Greeks from the Black Sea area and the Caucasus fleeing from the new Bolshevik régime's repressions. A country with 4.5 million inhabitants faced the arrival of 1.3 million refugees. At the same time, the 'population exchange' provided for the departure of Turks and Albanians.

The third phase of ethnic homogenization includes the decade between 1940 and 1950, marked by the Nazi policy of annihilation, transfer, and expulsion of whole ethnic groups and by Stalinist deportations and purges. Along with the holocaust of the so-called 'transnational minorities,' that is, the Jews and Roma, there were massive population movements in Central and Eastern Europe. Eleven and a half million Germans were expelled from the Ostgebiete (eastern territories) while three million Poles, particularly from the regions absorbed by the Soviet Union after the Second World War, were settled in Silesia and in the southern portion of eastern Prussia. Thus Poland became an almost monoethnic country.

The treaties between Czechoslovakia and Hungary, and between Hungary and Yugoslavia, which also provided for reciprocal population exchanges, date back to the same period. Finally, Stalin consolidated his conquests in the western part of the Soviet Union through a policy of planned mobility. This involved the deportation of populations considered accomplices of the enemy and therefore traitors of the great patriotic war (Latvians, Lithuanians, Estonians, etc.) to Siberia or central Asia. It also involved replacing them with more 'reliable' immigrants, mainly of Slavic origin.

The fourth virulent phase of ethnic homogenization is the wave of ethnic separations that has devastated Central and Eastern Europe over the past 25 years. It can be traced back to Socialist Bulgaria with its approach to minority problems. In the second half of the 1980s, the Bulgarian solution was to expel and/or forcibly assimilate ethnic Turks. The phase continued with the disintegration of the three countries born after the First World War through a multiethnic and multinational logic: Yugoslavia, the Soviet Union, and Czechoslovakia. The resulting new and old states are all based on the nation-state principle. This latest wave of separations, which aims at the homogenization of territories with highly differentiated ethnic structures and claimed by one or more nations, continued in the 1990s in Bosnia and Kosovo, and may not yet have come to an end, particularly in the Balkans and former Soviet Europe.

Postnational Europe in the Making?

Over the final 50 years of the twentieth century, there were major population movements in Europe; this is the most outstanding characteristic of this period. These migrations for economic (job seekers) or political reasons, namely humanitarian (asylum seekers), have affected Western Europe more than Central–Eastern Europe. Until 1989, Soviet hegemony in this area allowed only a limited and often planned mobility, even though immigrant laborers were not totally lacking (Vietnamese in Bulgaria, former Czechoslovakia, German Democratic Republic, and the USSR as well). Within the EU and its previous community institutions, a gradual, albeit slow, frontier abatement among member states eased transnational mobility. From the end of the 1950s, unprecedented numbers of laborers from the Mediterranean and Southeast peripheries (Italy, Spain, Portugal, Greece, and the former Yugoslavia) reached the core (France, Germany, Austria, Switzerland, Benelux, the United Kingdom, and Scandinavia). Here they found jobs in industry and in fields that are not sought after by the local population because they are considered low-status activities. From the 1970s, these immigrants were joined by an increasing number of laborers from the Mediterranean area bordering on the Old Continent (Turkey and Maghreb). Although, so far some countries, such as Germany and Switzerland, challenge this designation, northwestern European countries became immigration societies in this period, notwithstanding strict measures introduced in the early 1970s regulating foreigners' permanent entry.

The circumstances in Euro-Mediterranean former emigration societies (Italy, Spain, Portugal, and Greece), which in the meantime have become immigration countries, are slightly different from Northwestern Europe's situation. Migration is mainly from so-called Third World countries (sub-Saharan

Africa, Southeast Asia, China, the Indian subcontinent, Latin America, and so forth) and from the continent's most underdeveloped areas (Albania). From the end of the 1980s, however, what became known as mass unemployment worsened in all of Western Europe. Therefore, recruitment of foreign workers fell drastically while political and humanitarian immigration increased.

At the same time, large numbers of migrants reached the core from non-European regions and from former Socialist bloc countries after the fall of the Berlin Wall (1989) with the subsequent opening of frontiers. Facing a difficult sociopolitical transformation and an unstable economy, Central–Eastern Europe is not the preferred destination for these migrants, who regard it only as a stopover on their way to Western Europe. Therefore, former 'Real Socialism' countries become a temporary buffer zone.

These migratory circumstances have deeply changed the present Europe's setup, calling in question the sociocultural order created by nation-states based on the ideal of a monoethnic territory. The growing presence of diasporas, transnational groups, creolized communities, and deterritorialized collectivities in Europe's social and cultural setting, plus minorities' emphatic claims and demands (linguistic, religious, and ethnic), have fired discussions on nation-state adequacy and the need for postnational organizations with new types of transnational, flexible, or multiple citizenships, as Ferry (1992), Pierré-Caps (1995), Kleger (1997), Ong (1999), Linklater (2002), or Sassen (2002) foresee. However, such projects might be taken into serious consideration only as the twenty-first century progresses.

For the time being, globalization in Europe has led neither to a neoliberal homogenization as suggested by Fukuyama (1992) nor to a McDonaldization of society as conceived by Ritzer (1996, 1998). Europe has instead experienced a *glocalization*, as postulated by Robertson (1995). More to the point is the resurgence of political regionalisms. Current versions of political regionalisms, contrary to those of the 1970s, can no longer be likened to ideology or opinion movement rebellions if not mass uprisings. Instead, they involve arrangements and compromises with the national states' governments. Hence, present-day regionalisms are not so much *counter*- as *co*-phenomena. By now, the term 'regionalism' also has its place in the common parlance of politicians and bureaucrats. We need only mention phrases such as 'the Europe of regions' or terms as 'devolution,' 'federalism,' and 'autonomism.'

Present-day regionalisms in Europe are political orientations seeking accommodations or compromises with globalization through negotiations. They are grounded in the appeal to local identitary belongings in an attempt to adapt to radical sociostructural changes triggered and/or imposed by the globalization process. Furthermore, they are social strategies aiming to overcome globalization-induced difficulties and problems via the mobilization of local societies whose members think and/or believe that they belong to the group because of specific shared qualities. Finally, regionalism is a response in line with national states' gradual cession of sovereignty to social, political, and economic institutions of global governance.

Admittedly, between the gradual cession of national states' sovereignty and regionalistic claims, there is now a dialectic relation that generates new political setups through constant accommodations, in some cases even based on a lasting, though often shaky, power sharing, both locally and nationally. Not to mention that nowadays in Spain or Romania, Italy or Bulgaria, governing is a difficult task without the support of parties advocating regionalism.

In the European context, we can distinguish between ethnic regionalism and cosmopolitan regionalism. By ethnic regionalism we mean a sociopolitical movement striving to build an imagined collectivity whose belief in commonality is based on ethnic criteria regarded as qualities unique to one's own group, such as origin, ancestry, history, traditions, culture, religion, language, and last but not least, territory.

At first glance, cosmopolitan regionalism by its very nature should be considered postethnic (in line with the definition of this term by David Hollinger, 1995), transboundary, and transnational. In principle, this type of regionalism:

- should make boundaries between groups involved in these types of regionalism more flexible, if not indeed variable,
- should allow the individuals involved to have plural belongings,
- should accept hybrid identities for these same individuals.

Cosmopolitan regionalisms, at least in principle, have a 'social imaginary' that certainly lies outside that of the national state; however, as far as their currently inadequate political realization is concerned, for the time being we can only be skeptical.

As an example, consider the Euroregions, which by juridical definition are transboundary and thus transnational. These were meant to be institutions in charge of carrying out cosmopolitan and postethnic projects at a local level. In most cases, however, despite the proliferation of these projects and some instances of zeal and initial enthusiasm that led to belief and hope in the formation of bottom-up participation movements, the top-down aspect was strikingly prevalent. This demoted the Euroregions to a question of bureaucracy and technocracy for the most part, ultimately leading local societies to back out of the projects.

In the main, realized regionalisms are ethnoregionalisms grounded in the 'social imaginary' stemming from the national state, and moreover from an ethnic-based one. Ultimately, as the emblematic cases of Catalonia, Galicia, Spanish Basque Country, Corsica, Flanders, Walloon Provinces, Scotland, and 'Padania' show, until now the ethnoregionalisms resulting from globalization have been unable to express political models as alternatives to those of the classic national state (Calhoun, 2007).

Euthanasia

Dieter Birnbacher, Institut für Philosophie, Heinrich-Heine-Universität Düsseldorf, Düsseldorf, Germany

Abstract

'Euthanasia' is derived from Greek words meaning 'dying well' or 'good death.' First used by Greek poets from about 400 BC onward, the term was adopted by Greek and Roman philosophers and historians to denote a death that comes quickly and without great and prolonged suffering. Today, the term is primarily used for interventions by others to ease death. The article addresses both questions in the ethics of euthanasia and questions concerning the evolving research on the practice of euthanasia, mainly in European countries. In order to structure the discussion, it distinguishes five meanings of 'euthanasia': (1) caring for the dying by relieving suffering psychologically and medically, and by spiritual assistance; (2) letting die suffering patients by not artificially prolonging life; (3) actively hastening death to shorten suffering by assisting patient suicide, by voluntary or nonvoluntary active euthanasia; (4) withholding life-sustaining treatment from a patient in a persistent state of unconsciousness; and (5) ending the lives of children and adults seen as a burden to society or to their families.

For many reasons, during the last 20 years, euthanasia has increasingly become a subject of social scientific research. Analogously to public opinion about sexual morality, public opinion about the morality of medical end-of-life practices seems to undergo rapid changes, partly in consequence of the continuing prolongation of the human life span by medical progress and social improvements, partly in consequence of the decreasing influence of religious traditions on social attitudes and legislation, at least in the industrialized world. Living wills are increasingly used by patients to provisionally exercise their constitutional rights to self-determination in case they lose their capacity to give valid consent to medical treatment in the future, and they are increasingly backed up by institutional safeguards (cf Council of Europe, 2004). Living wills are increasingly made the subject of explicit legislation, and more and more hospitals include living wills of patients in their conditions of admission. Furthermore, social science research is urgently needed in order to assess the far-reaching empirical claims made by the parties on both sides of the political controversy: the claim, on the one hand, of right-to-die societies that the personal preferences concerning the time and mode of dying continue to be insufficiently respected by legislators and medical societies, and the claim, on the side of conservatives, that a more liberal legislation creates a slippery slope to morally inacceptable misuse and abuse. Psychological and social research in the end-of-life context, however, faces particular difficulties and ethical challenges. Anecdotal evidence suggests that physicians tend to be secretive about their treatment of end-of-life patients and that official statistics tend to be unreliable, particularly in countries with laws prohibiting even less controversial forms of euthanasia such as termination of treatment. Furthermore, research in end-of-life contexts is hampered by severe ethical restrictions. Patients at the end of life are generally highly vulnerable and research involving them may be felt as a problematic intrusion.

The article addresses both questions in the ethics of euthanasia and questions concerning the evolving research on the practice of euthanasia, mainly in European countries. In order to structure the discussion, it distinguishes five meanings of 'euthanasia': (1) caring for the dying by relieving suffering psychologically and medically, and by spiritual assistance; (2) letting die suffering patients by not artificially prolonging life; (3) actively hastening death to shorten suffering by assisting patient suicide, by voluntary or nonvoluntary active euthanasia; (4) withholding life-sustaining treatment from a patient in a persistent state of unconsciousness; and (5) ending the lives of children and adults seen as a burden to society or to their families.

Introduction

In the original Greek, 'euthanasia' meant 'good dying' (*eu thanatos*). First used by Greek poets from about 400 BC onward, the term was adopted by Greek and Roman philosophers and historians to denote a death that comes quickly and without great and prolonged suffering. The term 'euthanasia' was not used for the intervention, medical, or otherwise, to ease a patient's death or to end his or her suffering. Such intervention cannot, however, have been uncommon in antiquity, since assisting a patient's suicide was explicitly ruled out in the so-called Hippocratic oath. Whoever swore this oath (probably the members of a small Pythagorean sect of physicians) committed him- or herself to "give no deadly medicine to anyone if asked, nor suggest any such counsel."

In modern times, the meaning of the concept has considerably changed. Though its core meaning of 'good dying' was preserved, it no longer refers to the quality (however defined) of the process of dying as such, but to the cooperation of someone else (the physician, the priest, or others) in making death easier for the dying. Francis Bacon, in a passage of *De dignitate et augmentis scientiarum* (1623), was the first to distinguish two kinds of assistance to which, according to him, a dying patient has a claim, *euthanasia interior*, the "spiritual preparation of the soul" for death and *euthanasia exterior*, "whereby the dying may pass more easily and quietly out of life" (Bacon, 1857: p. 387). Bacon's point was that the purely spiritual preparation provided by the priest was not enough but should be supplemented by medical means to ease the dying process.

By this token, Bacon suggested the introduction of what is now called palliative care, the systematic effort to relieve, by medical means, pain, and other symptoms causing suffering to the dying. Euthanasia in this sense, Bacon insisted, was not only a natural part of the duties of the physician but also a requirement of plain humanity. Though psychological and spiritual assistance in dying continues to be recognized as one of the central elements in the care for the dying (often, however, neglected in practice), the modern concept of euthanasia includes the 'easing of death' only in so far as this is effected by the application or nonapplication of medical means.

The term 'euthanasia' is not commonly applied to procedures by which the death of a patient is eased by any action or omission the patient carries out without the direct or indirect involvement of a second party, such as suicide in a nonfinal state of a progressive disease or the refusal of nutrition and hydration with the aim of hastening death (Chabot, 2012).

Five Types of Euthanasia

The principal meanings of the term 'euthanasia' in ethical and legal discussion correspond to the various forms in which medical assistance in dying can be given:

1. Relieving suffering by palliative care, e.g., by giving pain-killing drugs and suppressing symptoms such as vomiting, unrest, or feelings of suffocation. Palliative care for the dying is rarely referred to as 'euthanasia' in the absence of the more typical practices (2) and (3). However, the term 'indirect euthanasia' is generally applied to cases in which medical interventions aimed at relieving suffering (such as administering drugs, sedating a patient with narcotics, or operating on a patient to make the dying process more tolerable) hasten a patient's death.
2. Withholding life-sustaining medical treatment (either by not initiating treatment or by terminating it at some point) where this implies that the patient dies at an earlier date than he or she would if treatment were continued and where the intention is wholly or primarily to reduce the patient's suffering. This form of euthanasia is commonly referred to as 'passive euthanasia,' irrespective of whether withholding or withdrawing life-sustaining treatment is explicitly requested by the patient. The term 'passive' is often taken to suggest that this variant of euthanasia is legitimate (in contrast to 'active' forms of euthanasia), which, however, is a misunderstanding. 'Passive' is in itself value-neutral and refers to nothing but the fact that the death of the patient is primarily caused by his or her bad state of health and not by any kind of intervention.
3. Actively hastening death to shorten suffering, either by killing the patient ('active euthanasia'), by assisting the patient to kill himself ('assisted suicide'), or by putting the patient in a prolonged state of unconsciousness (e.g., by giving him or her a strong dose of narcotics) ('palliative sedation'), with the intention to withdraw life-sustaining treatment while the patient is in this state.

Interest in euthanasia of these various types has grown in proportion to two historical developments: the growth of the resources of modern medicine and its increased capacity to maintain life functions in states of terminal disease; and the growing interest of patients to decide themselves about the way they want to die, especially where physicians tend to preserve life in situations of imminent death at the cost of severe suffering.

Political impulses toward making euthanasia a patient right continue to come primarily from the euthanasia and 'right-to-die' societies that have developed all over the world (the British 'Voluntary Euthanasia Legalization Society' was founded in 1935, the 'Euthanasia Society of America' in 1938). They vary, however, in the forms of euthanasia they want to see legalized by law and professional codes. All societies advocate the extension and improvement of psychological and palliative care (including, for the most part, palliative sedation) for the dying as well as termination of treatment where this is explicitly requested by the patient (cf the manifesto of the World Federation of Right-to-Die Societies, 2013). The differences between them concern the extent to which they advocate voluntary active euthanasia (as well as the related forms of assisted suicide). While for the Hospice movement (Yennurajalingam and Bruera, 2011) it has become partly a matter of principle to reject active euthanasia (and in many cases also physician-assisted suicide), most euthanasia societies demand the legalization both of (physician-)assisted suicide and active euthanasia under what might be called the "paradigmatic euthanasia conditions" (Birnbacher, 2004): (1) the patient is in an irreversible state of disease or impairment of functioning, (2) the patient suffers intolerably, (3) the patient explicitly wishes to die, (4) this wish is not only momentary but persistent. Concerning (1), some societies restrict the definition of disease to clear cases of somatic disease such as end-stage cancer, whereas others, such as the Swiss society 'Exit,' include also psychiatric diseases such as major depression and schizophrenia. A number of societies, however, favor assisted suicide over voluntary active euthanasia as a more unambiguous expression of the patient's autonomous will. At present, an officially approved and legal practice of active euthanasia exists in the Netherlands, Belgium, and Luxembourg, an officially approved and legal practice of physician-assisted suicide in Switzerland and in the states of Oregon, Washington, Montana and Vermont, USA.

The common element of the variants (1) to (3) of euthanasia is that the primary and ultimate aim of giving euthanasia is the relief of suffering, either from physical pain or from other inconveniences of the patient's condition. Shortening the life of the patient is either intended as a means to that end (active euthanasia, passive euthanasia, assisted suicide) or accepted as a side effect (indirect euthanasia). This common element is lacking in practices (4) and (5).

4. Withholding life-sustaining treatment from a patient in a persistent state of unconsciousness (as in the so-called *coma vigile*) with the resulting (and mostly intended) death of the patient. In cases of this sort, the intention cannot be to relieve the patient's suffering because an unconscious patient cannot experience suffering. (There is, however, an unclarity on this point. In some cases, a residual form of consciousness, the so-called minimal conscious state can be diagnosed from the patient's behavior and brain scans.)

Euthanasia in these cases is generally justified either by the patient's presumed will not be kept alive in a persistent state of unconsciousness (as documented, e.g., by an advance directive), by the insistence of the family distressed by a treatment they often see as degrading and contrary to human dignity, or, in advanced stages, by considerations of medical futility (studies have shown that the probability of an 'awakening' from a so-called 'vegetative state' is about 1% after 1 year). Relevant jurisdiction in the US and the UK shows a tendency to allow the withdrawal of life-sustaining treatment after several years of 'persistent vegetative state' given the approval of the family.

5. Ending the lives of adults and children seen as a burden to society or to parents. In German-speaking countries, the German equivalent to the term 'euthanasia' inevitably evokes the National Socialist practice of killing children with malformations and the inmates of psychiatric hospitals and is normally replaced, in reference to practices (1)–(4), by the term *Sterbehilfe* (aid in dying). Moreover, memories of the NS-'Euthanasie' explain at least part of the violent resistance, especially in German-speaking countries, to philosophical justifications of infanticide (such as by Peter Singer and Helga Kuhse) (Kuhse and Singer, 1985; Singer, 2011: Chapter 6). The motives behind the killing, with the cooperation of their physicians, of 70 000 patients of psychiatric institutions in Germany from 1940 to 1941 were partly economic (one criterion of selection was whether patients were able to work), partly an ideology of racial purity. After stopping the active killing in 1941, a further 90 000 patients were exterminated by 'softer' methods such as malnutrition (Benzenhöfer, 2009: Chapter VII, 3). Calling these killings 'euthanasia' was a deliberate euphemism, as was the term *lebensunwert* (unworthy of living) used by the authors Binding and Hoche in a seminal book as early as 1920 and suggesting a poor subjective quality of life (the contrary of 'a life worth living') but in fact expressing an objective judgment about the usefulness of a life to society. Ideas of a selective killing of 'useless' lives have their roots in the Social Darwinism of the late nineteenth century, though there are important earlier philosophical models. A rigid eugenic policy involving compulsory abortion and exposure of 'weak' children (probably on the Spartan model) were part of Plato's model state in the *Republic*. A curious blending of euthanasia in the sense of relieving suffering and euthanasia in the sense of getting rid of people seen as a burden occurs in Thomas Morus' *Utopia* (1516), where priests and state officials persuade the terminally ill to kill themselves rather than to 'survive their own death.'

Ethical Problems

While euthanasia in sense (1) is almost universally accepted and euthanasia in sense (5) almost universally rejected by medical ethics and medical law, ethical and legal discussion of euthanasia in each of the other meanings is highly controversial both on the national and the international level. Moreover, the discussion often shows a particular emotional quality. There are at least four controversial issues:

1. How to resolve the conflict between the *principle of patient autonomy* and the *best interest principle* in euthanasia situations. According to the principle of patient autonomy, medical treatment (except in emergency situations) must be based on the informed consent of the patient. If the patient is unconscious or otherwise unable to give valid consent, physicians are required to take into account the presumed consent of the patient, as indicated by written or oral advance directives, by the views expressed by the patient about how he or she would like to be treated in relevant situations and what else can be inferred from the patient's beliefs and worldview. At the same time, the physician is also bound by the best interest principle, which says that he or she should further the well-being of the patient in the best possible way. This is generally taken to entail both prolonging the life of the patient as well as an obligation to relieve suffering even without an explicit request. Generally, this principle is taken to justify shortening the life of a patient with terminal illness wherever there is intense suffering even in the absence of a capacity to give valid consent, provided that the intention of the physician is exclusively or primarily directed at relieving suffering.

Problems arise whenever the two principles come into conflict, as when a patient refuses an operation that, in all probability, would save his or her life at an acceptable level of subjective quality of life, whereas following his or her refusal would lead to instant death. There is considerable consensus among medical ethicists that a medical paternalism (i.e., treating the patient against his or her will, see Häyry, 1991) is objectionable even in cases of markedly 'unreasonable' patient wishes except when there is evidence that the patient is not sufficiently informed about his or her prospects, that his or her will is unstable, distorted by neurosis, psychosis, or excessive affect, or is alterable by additional information and argument. Though, on the best interest principle, the physician is called upon to persuade the patient to revise his or her decision, it is widely agreed that the physician should not resort to biased information, persuasion or even deception to change the patient's will, since this would undermine trust and infringe patient autonomy no less than compulsory treatment.

2. Whether actively discontinuing treatment (e.g., by turning the switch of a respirator) is normatively equivalent to strict inaction (e.g., by 'freezing' oxygen pressure at a level that is insufficient for the patient to survive). Ethicists and lawyers predominantly take both modes of action to be normatively equivalent. They see no morally significant difference between 'active' and 'passive' discontinuing nor between not starting treatment and terminating treatment. (Discontinuing treatment with the result or the intention of a patient's death in a euthanasia situation generally counts as 'passive' even if involving positive action because the state of the patient is merely restored to the condition in which it was before treatment.) There is, however, a considerable psychological difference. As a rule, physicians and nurses find it easier to let a patient die 'passively' by strict inaction. The reason is that, in this case, causality is attributed primarily to factors other than one's own behavior. This is markedly different whenever the death of

the patient follows more or less immediately on an active termination of treatment.

3. Whether active killing should be allowed to doctors (or to others) in euthanasia situations. Voluntary active euthanasia, i.e., actively killing a patient to end his or her suffering on the patient's explicit wish is an attractive option because of substantial doubts whether all states of suffering in the last phase of a patient's life (e.g., in some forms of end-stage cancer) can be effectively relieved by discontinuing treatment and/or palliative measures. Furthermore, many of the ethical arguments against voluntary active euthanasia on the level of principles suffer from the fact that they attribute much more normative weight to the distinction between activity (killing) and passivity (letting die) than is thought acceptable, and indeed desirable, in other medical contexts. In these contexts, the physician usually has not only a duty not to harm but also a duty to treat. In particular, the question arises how the acceptance of indirect euthanasia (which also involves active intervention) by most legislatures can be made consistent with the rejection of voluntary active euthanasia. The crucial difference seems to be that death is accepted as a side effect in the former case, whereas it is not held to be acceptable as a means to reducing suffering in the latter case. This difference has been regarded as highly relevant by the so-called doctrine of 'double effect' rooted in Catholic moral theology, which puts much ethical weight on intentions and less on consequences. This principle survives, as it were, in the legal treatment of euthanasia, whereas it is not generally accepted by most legal systems in other contexts.

More compelling arguments against legalizing voluntary active euthanasia are pragmatic considerations of potential misuse and abuse. Establishing a practice of active euthanasia risks that the autonomy of the patient is overruled by the wishes of relatives, the standards of the medical profession, and the interests of society. Due to a program of continuous survey research about actual euthanasia practice in the Netherlands, it was found out that in the Netherlands that along with a publicly approved practice of voluntary euthanasia (2.2% of all deaths in 2001, 2.8% in 2010), there has been an undeclared practice of nonvoluntary euthanasia that deliberately disregarded the procedural rules laid down by the Royal Dutch Medical Association. Though far from proving that a practice of voluntary euthanasia necessarily has a practice of nonvoluntary euthanasia in its wake, the opponents of the legalization of active euthanasia have a point in quoting the "Dutch experience" as a warning (see, e.g., Thomasma and Marshall, 1998). It is true, a majority of medical ethicists think that palliative sedation and physician-assisted suicide are, wherever possible, preferable as alternatives to active euthanasia, the former because it is interpreted as a purely palliative measure and the latter because it goes further than active euthanasia in asserting the autonomy of the patient (Quill et al., 1997; Orentlicher, 1998). However, since palliative sedation is frequently applied together with the withdrawal of artificial nutrition and hydration (e.g., in the Netherlands, cf Centraal Bureau, 2003: p. 67), it often goes together with the intention to hasten the death of the patient no less than the more controversial forms of euthanasia. On the other hand, in the Netherlands active euthanasia is often preferred over assisted suicide because of physical weakness or incapacity of patients (Onwuteaka-Philipsen et al., 2003: p. 4).

Social Science Research on Euthanasia

Social science studies about the practice of passive and active euthanasia have begun to be undertaken only recently, partly after the model of the Dutch Remmelink report, which was done in 1990–91 at the request of the Dutch government in preparation of euthanasia legislation. This nationwide study included interviews with 405 physicians (carried out by 30 experienced physicians and five other academics) and a questionnaire study with the physicians of a sample of 7000 recently deceased persons. The main result of this study was a surprisingly high incidence of euthanasia in the Netherlands prior to regulation. Fifty-four percent of the physicians interviewed confirmed that they had practiced active euthanasia or assisted suicide on the request of patients and a further 34% said that they could conceive of situations in which they would be prepared to do so (van der Maas et al., 1991: p. 669). Twenty-seven percent said that at some time they had ended a patient's life without his or her explicit request and a further 32% said that they would be prepared to do so under appropriate circumstances. The study was repeated every 5 years showing that the situation in the Netherlands has not substantially changed up to now (van der Maas et al., 1996; Onwuteaka-Philipsen et al., 2003).

Substantially lower figures were found in an Australian and a British questionnaire study in which 29% (12%) of all doctors who returned a completed questionnaire confirmed that they had taken active steps to end a patient's life. A large proportion of the British respondents (46%) was reported to say that they would consider taking active steps to bring about death if it was legal to do so (Kuhse and Singer, 1988: p. 623, Ward and Tate, 1994: p. 1332). A metastudy of all relevant surveys of the period 1990–2010 showed, however, that this estimate was exaggerated and that the value is no larger than about 25% (cf McCormack et al., 2012: p. 26).

Legislatures and medical associations continue to differ greatly in the practices they legalize, tolerate, or prohibit (Heide et al., 2003; Birnbacher and Dahl, 2008). A striking example is that of the neighboring and culturally highly similar countries the Netherlands and Germany. Differently from the Netherlands, in Germany active euthanasia is still largely a political taboo in spite of a high approval (about 70%) by the general population. The only questionnaire study done so far showed that the proportion of physicians practicing active euthanasia was maximally 5% (Kirschner and Elkeles, 1998: p. 251). In contrast to voluntary active euthanasia, physician-assisted suicide is not a criminal offense in Germany but declared unethical and correspondingly sanctioned by the medical associations. According to a recent survey, however, more than one-third of German physicians can think of conditions under which they would consider assisting a patient suicide. The situation is, again, different in Switzerland where voluntary active euthanasia is legally prohibited but where assisting suicide is legally prohibited only in cases of self-serving motives

and is generously tolerated by the medical associations and by state authorities. The resulting contrast in legislation between Switzerland and neighboring countries has led to the new phenomenon of 'euthanasia tourism,' especially with the establishment of organizations in Switzerland that, differently from older Swiss organizations such as Exit, offer their services to patients from abroad.

Evangelical, Revivalist, and Pentecostal Religions

Abstract

This article points out the connections between three of the great themes of modernity – the interplay between Protestant Christianity and the universalizing tendencies of modern culture and modernist revivalism. Not only did the Reformation result from and encourage the rise of capitalism, it provided cohering worldview ideologies and organizational principles which contributed to modern science, European colonialism, and expansion by migration, revival, missions, the formation of imperial professionalism, and a global vision which relativized national identities. It is of continuing interest to sociologists not just because of the remarkable global spread of Pentecostalism, but because of its implications for secularization theory.

While 'globalization' as a concept arose as a fiscal planning tool in the 1950s, its extension as an explanatory concept for the sort of territory previously covered by such frameworks as 'world systems theory' dates from the 1970s. At the time of writing, Roland Robertson and Peter Beyer are the key writers in the area as it relates to religion. Indeed, Robertson's pioneering framework arises out of the conundrum which religion presents for standard modernization theory. The rise of Islamic and other forms of religious fundamentalism denies the linear rationalist assumptions of modernization theory and such offspring as secularization theory, which suggest that regional difference and religious conviction should be passing away in the face of rational technical systems and the homogenization of culture. Robertson has since then further articulated the theory through the concept of 'globalization,' which allows for simultaneous global homogenization of culture and local reassertions of difference. Robertson's theory that cultural forces move faster than political and economic forces has received considerable support from historians and analysts of Christian missions, which have noted that the indigenization of Christianity has historically been faster and deeper in Asia and Africa than the movement of formal missionary and colonial structures. In South America, by contrast, there is a body of opinion which states that the combination of state apparatus and church extension actually retarded the extension of Christianity. It is clear, then, that globalization theory is vital for the understanding of the expansion of Christianity generally, just as the study of the expansion of Christianity is vital for understanding the processes of globalization.

While a slow starter to get into missions, evangelical Christianity began to articulate an increasingly sophisticated global vision from the late 1600s, with the rise of the Pietist movement. As Lewis has noted, Pietism restored a sense of personal call to Protestant orthodoxy which, through agencies such as the University of Halle and Moravian missions, expressed itself in a growing internationalism. The correspondence of Zinzendorf, the migration of Moravians, and missionary outreach to Russia, Greenland, and India, created networks and examples of successful missions which informed the expanding networks of new settler societies and expanding capitalism. It was on a trip to the New World that John Wesley, for instance, first ran into Moravians, who, through the influence of Peter Böhler, provided the synthesizing principle to Wesleyan eclectic theology and practice which in turn made it a vibrant missionary force. It was likewise among Scots-Irish and Dutch settlers in the New World that religious revival produced the combination of Protestant theology and religious experience which has become known as 'Evangelical Christianity.' Definitions differ, usually with personal affiliation, but a standard definition of Evangelicalism offered by David Bebbington locates the movement in a quadrilateral of theology and praxis involving activism, cross-centeredness, Bible-centeredness, and conversionism. The fact that nothing like the French Revolution occurred in England helped legitimize the movement as a source of social and cultural stability. The inner energies of the movement, combining a universalizing crucicentrism and biblicism, with conversion-oriented activism, meant that the tens of thousands of converts to the Evangelical Awakening on both sides of the Atlantic provided a vast pool of willing support to the evangelical program to change globalizing British society. The leaders of the movement – in particular William Wilberforce, Lord Shaftesbury, the Clapham sect, and Selina, Countess of Huntingdon – were able to draw upon these networks of support in a dynamic program of social activism over the century 1750–1850. This activism arguably provided important impulse force to the processes of globalization, just as globalizing Western economies provided important resources and opportunities for evangelical expansion and change.

Protestants from Luther's time were faced with an expanding globe in tension with an increasingly outmoded ecclesiology. While, during Luther's own lifetime, Diaz rounded the Cape of Good Hope (1488), Columbus was driven west in pursuit of a millennial vision to land on the shores of America (1492), and other parts of the world were opened to Western influence by da Gama, Cabot, Cortes, Magellan, and Pizarro, Protestants were combining with increasingly nationalistic ruling classes (the nobility in Germany, bourgeoisie in Switzerland and The Netherlands) to reinstitute the 'Christendom' ideal within the national churches of rising nation states. While Catholic empires ruled the seas, Protestant missions were restricted to Europe. While the theology became increasingly arid and formalized, the impact of these churches was to reinforce the nexus between nationalism and capitalism.

Capitalism expanded during the period through royal chartered companies, combining national expansion and capitalist enterprise. Halle Pietism specifically used this link to expand into Russia, just as Puritans used the chartered company to establish themselves in Massachusetts Bay. The CMS first fought with and later used the East India Company in Asia, while the Claphamites moved into West Africa on the tails of colonization companies. While Weber's 'spirit of Protestantism' has been revised and attacked in some quarters, it is nonetheless a useful heuristic when viewing the interaction of shipping, chartered, and colonization companies on the one hand, and missionary agencies on the other.

Protestantism provided an 'inner fascination with the world,' and evangelicalism adopted the same fascination and extended it. There has been considerable work done, for instance, on the link between enlightenment and Evangelicalism, indicating that Evangelicalism, through its commercial and missionary emphases, was a major carrier of rationalizing Western concepts of time and space into the rest of the world during the late nineteenth and early twentieth centuries. Not only did Wesley proceed on the assumption of an 'inner enlightenment,' using both the vocabulary and technologies of enlightenment to further the evangelical cause (he was, for instance, an assiduous publisher), but Puritan and evangelical input into the sciences from the sixteenth to the nineteenth centuries was immense. Clergy were not only involved in agencies such as the Royal Society, but were key suppliers of information to enlightenment projects such as the social sciences. (Malcolm Prentis, for example, has demonstrated the link between clerical collection and the construction of an international culture of research in anthropology.)

The logical place to look for the globalizing influence of evangelicalism is through the agency of missions. The marginality of missions at the beginning of the nineteenth century demonstrates the close association of evangelical expansion with Western expansion. By 1800, North America was subject to European settlement, but only on the eastern half and the western rim of the continent, and though there was no real challenge to Hispanic hegemony in South America, Christianization had not really pierced deeply below the surface of the indigenous and emerging plantation cultures. The impact of missions in the Indic, wider Asian, and Muslim worlds was negligible. Obviously, then, developments in the nineteenth century were critical for the development of global Christianity in our own period. Europe at the time was weak and divided religiously. The industrial revolution encouraged both concentration of the sort of wealth which could capture foreign markets and provided the scientific curiosity and the speed of travel to take advantage of new opportunities. While most European expansion in the eighteenth century had been mercantilist in nature – with small colonies of isolated Europeans trading with Asian nations in sealed cantons such as Shanghai, Macau, and Hong Kong – the nineteenth century saw a shift toward extensive settlement and active domination of local politics. At least in part, this was because it was now technically possible, with advances in communication and military hardware, to dominate other less advanced cultures. So Britain absorbed India, Burma, and Ceylon into a new Empire, France annexed Indo-China, and The Netherlands finalized its annexation of Indonesia. Other European powers founded colonies, such as the German colonies in PNG, and annexed parts of Africa, such as Togoland, Southwestern Africa, and the like. At least for the British, Stanley argues that there was a consistent imperial impulse to British society, but no plan of conquest, most acquisitions having been gained in order to protect trading rights. Formal control was never exercised when the much cheaper form of informal control could be used, and it was the increasing need for formal control, driven by the intensified competition of European powers for global resources, which drove Britain to acquire and then defend India as the keystone in its defense of the East.

In terms of the other global religious cultures, evangelicalism also faced weakened opposition. One advantage of the time was that Islam was in retreat – in 1821 Greece was retaken, and from the 1830s European powers began dividing up Islamic parts of Northern Africa such as Morocco, Algeria, and Tunisia. Roman Catholicism at the beginning of the nineteenth century was under siege from the forces of modernization. With the eclipse of Portugal and Spain as imperial powers, increasingly the push for missions in the Catholic world came from France, Belgium, and (significantly for Australia) Ireland. While the Orthodox churches did not pursue much in the way of missions, despite the spread of the Russian Empire during this period, the Protestants, energized by the Evangelical revival, certainly did, both within and outside the English speaking world. Stanley suggests that, while there were agencies such as the Society for the Propagation of the Gospel with a missionary element to them, before the Evangelical awakening there was no consistent acceptance of the burden of foreign missions by either Anglican or Dissenting Protestants. Europe was the same. In 1810, for instance, a revival known as the Reveil spread out of Geneva and affected the French Protestant world deeply, leading to considerable missionary endeavor overseas. Norwegian revivals, most notably commenced by Hans Nielsen Hauge, a lay reader preaching in a way which was not legalized until 20 years after his death, energized Scandinavian missions to North America and later to South America. German missionaries, in the tradition of Halle and the Moravians, traveled all over the world. The interaction of these revival movements and missions can be seen in their common adherence to interdenominational agencies such as the Evangelical Alliance, which was founded in 1847, and held conferences in France, Belgium, Switzerland, Germany, Canada, Sweden, and the United States.

The model provided by the Alliance of a voluntary society was to become the classic form for Protestant missions. Many were formed at the prompting of chaplains and clergy traveling with army, trading company or political representatives. The first of them was the Baptist Missionary Society (1792), inspired by William Carey, who in turn had been inspired to mission by the accounts of the travels of such explorers as Captain James Cook in the Pacific. It was followed by the London Missionary Society (1795), the British and Foreign Bible Society (1804), the Wesleyan Methodist Missionary Society (1813), and many others. Because the Church of Scotland refused the requests of its Evangelical party to form their own missionary agency, most Scots siphoned off into other agencies, such as the LMS. In 1810, preceded by many small bodies dedicated to evangelizing First Nations' peoples,

the first American foreign agency was founded in the American Board of Commissioners for Foreign Missions.

The extension of evangelical missions had a number of major interactions with the growth of global society. The first was that, with increased need for personnel, the missions started their own Bible training institutions. These in turn legitimized the long-standing 'old dissenting' academies, supported religious emancipation and social reform, and acted to break down the exclusivism of the established church-linked universities. European states, at slower or faster rates, responded to this broadening of the religious franchise (among other secularizing tendencies) by stepping back from the official sanctioning of one form of religious truth or another. By the end of the century, most European states had become generally 'Christian' countries without confessional attachments, and many, in their colonies (particularly in Canada and Australia) were actively encouraging liberal democratic states. Not only did missions change the education of the increasingly vital professional class at home, but in exporting the Western educational model, also exported Western professional values into the nation states which began to arise in Asia, Africa, and the Pacific from the late nineteenth century. In exporting values such as professional disinterestedness, the importance of technical expertise, and basic human rights, a common culture was established which facilitated not only the spread of global society, but also (through preservation and re-skilling of Fourth World peoples) the means for local opposition to global homogenization. The specter of evangelical African bishops nay-saying advanced liberal proposals at a Lambeth conference, or Aboriginal evangelicals controlling the balance of power in the national assemblies of the United churches of Canada and Australia, have demonstrated the interactivity between evangelical missions and mediation of global culture.

The establishment of comity arrangements between evangelical missions in foreign countries highlights the second major interaction. The movement of religious traditions outside their national boundaries produced a relativization of their content and form, creating movements toward ecumenism based on 'common gospel' assumptions, diminishing the importance of liturgical and cultural tradition, and homogenizing the culture of international Christianity. This was imported back into the West as de-denominalization, and into Third World countries as 'alliance Christianity,' enabling Christianity to be described as a unitary object in contact with other world religions. This sense of relativization of form sparked concerns about relativization of truth, concerns expressed most markedly in the fundamentalism/modernism debates of the 1920s onwards.

Fundamentalism self-consciously identifies itself as a countermodernist movement, particularly in terms of theological modernism. Evangelicalism maintains something of this thrust, at the end of the twentieth century increasingly identifying itself as a counter-postmodernist movement. On another level, however, these debates can be seen as localized resistance to homogenizing forces at the global level, resistance seen most markedly in the general opposition of national evangelicals to agencies such as the World Council of Churches. In some cases, this meant the localization of evangelicalism into extreme nationalist forms. In most cases, however, especially after the rise of the National Association of Evangelicals in the USA and the Billy Graham Organization, the centrality of missions and a self-identity partly defined by contention for the faith caused evangelicals after World War II to take the same globalizing path that the WCC had already taken. This is reflected in the formation of agencies such as the Lausanne Committee, the World Evangelical Fellowship, and worldwide denominational fellowships such as the World Alliance of Reformed Churches. Particularly after World War II, these agencies provided the basis for expansion of English and, with increasing hegemony, American evangelicalism onto the world stage. By the 1990s, it was clear that denominations had become almost irrelevant to the self-definition of most evangelicals, and that localized megachurches were more important for agenda setting.

Likewise, evangelical missions had shifted from being denominationally and agency based to increasing integration with global movements in migration, occupation, and tourism. Short-term mission, and mission originating from countries in the 'South,' contribute nearly as much to the total Christian missionary workforce as do traditional, First World, agency based missions, and is likely soon to outstrip it.

Within these tendencies in evangelicalism in the nineteenth century arose the issue of 'revivalism.' Revivalism is a technical accommodation between the experience of revival, as formalized during and after the First Great Awakening by Calvinists such as Jonathan Edwards, and the utilitarianism implicit in early nineteenth century postenlightenment thought. The emphasis of Edwards and Wesley in defending the use of 'means' for the furtherance of religious revival were codified and extended during frontier revivals in New York State and the expanding American frontier. Not least among the codifiers was Charles Grandison Finney, whose *Lectures on Revival* became the great 'how to' book of the nineteenth century. Revivalism as it expanded from the USA to England, and then around the world (by way of church and migrant diasporas) developed an array of techniques to maintain the association between Christian mass evangelism and spiritual response. It became the tool of choice for many evangelicals as Western societies seemed to be slipping away from their commitments to national religious frameworks, a set of ideas crystallized in the premillennial theology of archetypal evangelistic movements such as the Brethren, Baptists, and Methodists. As a technical accommodation to utilitarianism, revivalism was a natural client and promoter of globalization, which was very largely fueled by the technical innovation of high modernist capitalism. So revivalism quickly spread by the development of Methodist itineracy into the big campaign evangelism of D.L. Moody, Alexander Somerville, Gypsy Smith, and the like. Such itineracy became global, as shipping, then automobiles, and then airplanes, brought other parts of the globe within reach. As communications technologies also improved – through telegraphed newspaper reports, international postage, radioed accounts, and finally television coverage (culminating in the global campaign by satellite of Billy Graham in 1996) – evangelicalism spread with revivalism to all parts of the globe. It is important to note in this regard the high degree of evangelical participation in modern technological enterprises, from Back to the Bible Radio, to the massive media empire of the Universal Church of the Kingdom of God in Brazil. This has been seen as a paradox by some commentators – it is less obviously so when revivalism's accommodation to

technological utilitarianism is taken into account. Though revivalism is not limited to evangelicalism (Catholic revivalism, for instance, or the adoption of revivalistic techniques by Hindu and Buddhist promoters in South and South-east Asia), and not all evangelicalism is revivalistic, it is clear that the two are blood relations and natural partners in many cultures around the world. At the same time, the fact that revivalism is a distillation of 'revival tradition' into a technological form which can thereby cross cultural boundaries makes it eminently transportable. For this reason, Edith Blumhofer has called the major global form of modern revivalism, pentecostalism, 'world evangelicalism,' because of its facility with communications technologies. The ability of pentecostalism to 'cast' itself as a communal form of thought through the abstracting processes of print media and CITs makes it a prime globalizing force. On the one hand, this makes for global expansion of evangelicalism through its revivalist and Pentecostal forms. On the other hand, the same process homogenizes its distinctives and causes it to adapt new local distinctives as it moves across cultures. The lack of a single center (unlike either Islam or Catholicism) is thus a great facilitator of growth, but is also the prime cause of internal dissension and fragmentation as various local evangelical cultures seek to adopt or invent normative centers which enable local communities and protect them from the effects of fragmentation. Neo-fundamentalism, Calvinist renewal movements in the Southern Baptist Convention, the Toronto and Brownsville revivals – each of these may be seen as the creation of new centers, which feed from the energies of globalization, and attempt to create islands of order amidst the chaos of global society.

In particular, evangelicalism as it stands at the beginning of the twenty-first century is clearly largely a two-thirds world phenomenon. As Piggin, Reed, and others have shown, revival is the inculturation of Christianity into local cultures. It is not too much to say, therefore, that the theology of revival, particularly as evidenced in Pentecostal revivalism since the 1950s, is a mainstream legitimating structure for the indigenization of Protestant evangelicalism. This is particularly evident in revivalistic outbreaks such as the East Africa Revival in the 1930s, the blossoming of Pentecostalism in Brazil and later in Argentina, and the Aboriginal revival commencing at Galiwin'ku in Australia's Northern Territory from 1978. In each case, evangelicalism struck new roots and found new accommodations with existing religious cultures which have in turn been exported into the global religious network.

While the East Africa revival had comparatively little experience of charismatic manifestations, Brazil and the Aboriginal revival have been highly charismatic in their combination of local and general characteristics. As Freston notes, the massive expansion of evangelicalism in that showcase of evangelical inculturation, Brazil, is likewise largely Pentecostal in nature. As he noted in 1998, a "survey of evangelical institutions in Greater Rio de Janeiro discovered that, of the 52 largest denominations, 37 were of Brazilian origin, virtually all Pentecostal. While only 61% of all evangelical churches were Pentecostal, 91% of those founded in the previous 3 years were" (Freston, 1998: p. 74). Of the 450 million 'evangelicals' and 750 million 'Great Commission Christians' estimated by David Barrett to exist in 1990, some 350 million could be counted within the Pentecostal or charismatic camp. It is clear that at the end of the twentieth century, evangelicalism's expanding edge was clearly Pentecostal/charismatic in nature, leaving the national traditions of the First World heartlands significant challenges of reinvention in their struggle to survive the disappearance of their defining ethnic and national boundaries.

Abstract

Edward Evans-Pritchard was a leading scholar of the twentieth century, holding the Chair in Social Anthropology at Oxford from 1946 to 70. Originally trained in history, Evans-Pritchard became famous for his outstanding ethnographic works on the Azande and Nuer peoples of the Anglo-Egyptian Sudan. In raising classic questions about the nature of reason, political order, and religion across the gulf then imagined between 'civilized' and 'primitive' societies, these studies brought a new sophistication into anthropological theory. He inspired a generation of followers whose work helped spread an international recognition for social anthropology, as an academic subject also relevant to practical affairs.

Background, Education, and Career Outline

Edward Evans-Pritchard was born at Crowborough in Sussex on 21 September 1902, the son of an Anglican clergyman. He attended Winchester College, a leading independent school in the British public school tradition, from which he entered Exeter College at Oxford University in 1921. His family background was less conventional, however, than this account might indicate, as his father was from Caernarvon and spoke Welsh, while his mother's family came from Liverpool. The history syllabus he followed as an undergraduate was itself on the conventional side, even for the period, but Evans-Pritchard then sought a more independent academic path and went on to study anthropology at the London School of Economics and Social Science. Through Seligman he embarked on several periods of field research in the Anglo-Egyptian Sudan from 1926 to 40, and in the early years of the Second World War was able to fashion opportunities for anthropological work on the Ethiopian border, in Kenya and in Libya, in conjunction with his military service. It was during the period from the late 1930s to 1940s that other key events in his life took place. In 1939 he married Ioma Heaton-Nicholls, daughter of the South African high commissioner in London; and in the early 1940s he was received into the Roman Catholic Church. On returning to Britain at the end of the War, Evans-Pritchard was appointed in 1945 to a Readership in Cambridge; and then in 1946, to the Chair of Social Anthropology in Oxford. Settling here, he and his wife raised their lively family of five children; while he came to play a key role in British academic life. He became president of the Royal Anthropological Institute (1949–51), a founder (1946) and later first life president of the Association of Social Anthropologists of the Commonwealth, and a fellow of the British Academy (1956). He retired in 1970, and his outstanding life's contribution was recognized with a knighthood in 1971. He died at his home in Oxford, on 11 September 1973.

Early Influences

During his time as an undergraduate at Oxford, Evans-Pritchard found his obligatory studies of mainstream history, mainly about kings and battles, somewhat constricting. However, Oxford already had the fine ethnographic collections of the Pitt Rivers Museum, and a tradition of related lectures, initiated by Edward Tylor in the 1880s. There was also provision for research and teaching in physical anthropology. Exeter College was already well established as a focus for anthropological activities in a broad sense, as a result of the enthusiasms of R.R. Marett, a practicing archaeologist with a strong interest in early forms of religion and society. He had been appointed as university Reader in Social Anthropology in 1910, but even by the 1930s had only developed an embryonic 'department'. However, in 1928, Marett became rector of Exeter College, and was able to maintain a lively stream of visiting speakers. Even as a student, Evans-Pritchard would have had the chance to meet many archaeologists and anthropologists there. It is extremely likely that he also attended the very popular lectures given in Oxford by the young philosopher–archaeologist R.G. Collingwood, ranging from topics in the archaeology of Roman Britain to questions linking academic philosophy with 'real life' experience. Evans-Pritchard was a little later to review Collingwood's *Roman Britain*, warmly endorsing what we would call today its 'sociocultural' approach to the everyday life and practices of the ordinary folk.

It was after Evans-Pritchard had embarked on his researches in the Sudan that he first had his own experience of teaching; this was at King Fuad University in Cairo from 1932 to 34, and during this time he published a series of critical, theoretical papers, which foreshadowed some of his mature work. In 1935 he was appointed to a temporary research lectureship in African Sociology back in Oxford, to work with Marett from time to time but also to use Oxford as a base for continuing field research. As Marett's expected retirement date approached (1936) there was much discussion in Oxford about the future of anthropology. A special interest was taken in this matter by All Souls College, which actively supported the establishment of a Chair in Social Anthropology, rather than simply 'Anthropology', on the grounds that enlightened governance required knowledge of the peoples of the empire, and would benefit from scholarly attention to questions of their culture, welfare, and interests (Davis, 2007). After a good deal of internal politicking, the chair was duly established in 1936, in conjunction with a fellowship at All Souls. The first appointee was A.R. Radcliffe-Brown, well known along with Malinowski for his pioneering the importance of first-hand fieldwork for

anthropology; he was also already known for his vision of the systematic nature of the (somewhat legalistic) principles governing the forms of social structure in small-scale societies. He could not take up the chair immediately but arrived in 1937 and began to pursue the cause of 'social' anthropology with a will. His efforts were inevitably set back by the outbreak of the War.

Evans-Pritchard's Field Research: The Analytic Ethnographer

Drawn by the promise of working with experienced field anthropologists, Evans-Pritchard moved on in 1924 from Oxford to the London School of Economics and Social Science. C.G. Seligman was already teaching there, and Bronislaw Malinowski arrived the same year. Seligman, with his wife Brenda, had been engaged in anthropological work for the government of the Anglo-Egyptian Sudan since 1910. They were beginning to seek others to continue their project, and Evans-Pritchard seized his opportunity. After completing a required survey in the southern Blue Nile region in 1926, he was allowed a free hand in embarking on his own project to study the Azande kingdoms of the equatorial forests bordering the Congo basin in the southwest. This field research, together with a series of visits between 1930 and 1936 to the very different region of the upper Nile flood plains inhabited by the Nuer, whose reputation for being a 'difficult' and elusive people far outweighed anything else known about them, laid the foundation for Evans-Pritchard's later career and his shaping of the discipline of social anthropology. A steady output of ethnographic articles mainly on the Azande and the Nuer also appeared through the 1930s, and indeed in the case of the Azande continued to appear throughout his life (a bibliography is provided in Beidelman, 1974). But it was the two remarkable monographs appearing at the end of the decade that confirmed Evans-Pritchard's outstanding contribution to the development of thematic, analytical anthropology. They were *Witchcraft, Oracles, and Magic among the Azande* (1937) and *The Nuer: A Description of the Modes of Livelihood and Political Institutions of a Nilotic People* (1940), both published by the Clarendon Press in Oxford, who successfully pleaded the need to obtain a subsidy in each case from the Sudan Government.

The Azande analysis (1937) immediately struck chords; Collingwood was one of the first to refer to it in print in his *Principles of Art* (1938). After the War, the book became widely influential in the debate opening up within philosophy over the socially and historically placed foundations of what could be understood as knowledge. It also resonated with the more flexible approaches being taken by historians toward the social context of 'witchcraft' phenomena in the European and American past. Because of its pace and well-constructed storyline, the book easily moved into teaching syllabuses and has always been popular with students. An abridged edition appeared in 1976, mainly to serve teaching courses, and has become a standard landmark in interdisciplinary discussions about the nature of knowledge, proof, belief, and evidence. The Azande and their doggedly 'rational' and clever way of monitoring and justifying the operation of their oracles (still quite surprising to many readers) have helped to define anthropology's contribution to such discussions. They have certainly entered almost every textbook on the subject published since the War. Ironically, however, the appeal of the Azande has more recently converged with new and easy forms of cultural relativism, which lead students to ask "Why should not the Azande believe in witchcraft, if it suits their way of life, and who am I to criticize them?" This is not Evans-Pritchard's line; on the contrary, he shows how most ordinary Azande themselves are not at all comfortable with the presence of witchcraft. It is those in powerful and privileged positions who focus on the idea, as the source of suffering and death, and turn their accusations on the relatively helpless. Sometimes cruel kings and princes ultimately control the oracles. Even at the household level only senior men have access to them, while women constitute a large proportion of the accused. Evans-Pritchard's analysis is explicitly set in a political and historical context that offers a more nuanced reading than that of simple relativism, and ultimately, it can be argued that this extra depth is what gives the text its lasting qualities.

The Nuer, as a people, and *The Nuer* (1940) as Evans-Pritchard's first book on them, next entered the life and language of academic anthropology. This was the first time that 'œcology' – now simply rendered as 'ecology' – had explicitly been selected for analysis in a field monograph. It was also the first analytical field study of the political principles behind patterns of hostility and alliance between apparently unrelated groups of mobile herders, here cast in a strong idiom of moral obligation invoked through the situational rhetoric of paternal descent crosscut by marriage alliances and maternal kinship links. Also for the first time, structured conceptions of space, and of time, were shown to have a social dimension and to constitute an overall framework of shared understandings within which political action was cast and could be 'read' by an observer. The book offered quite a different vision of 'social structure' from the empiricism of Radcliffe-Brown, and, significantly, has since been interpreted as a forerunner of the abstract 'structuralism' associated especially with Lévi-Strauss; Louis Dumont (in his introduction to the French translation, 1975) even claimed that it had not been properly appreciated by English-speaking anthropologists. *The Nuer* nevertheless served as model and inspiration to a wide range of field studies of 'segmentary' political systems both in Africa and elsewhere. With its successors *Kinship and Marriage among the Nuer* (1951a, written as a companion text and explicitly focusing on kinship rather than politics) and *Nuer Religion* (1956) it provoked a considerable industry of 'reanalysis', criticism, and comment. The point was often made that Evans-Pritchard's work was too closely associated with the interests of the (then) Sudan Government and with the perspectives of British colonial and imperial authorities generally, that this historical context was missing, and that his work and those ethnographies inspired by it were still in line with the 'structural functionalism' of Radcliffe-Brown. The secondary debates flourished in American and British anthropology for some decades until fresh field research began to alter the position of 'the Nuer' within anthropology by asking questions about them and their social world from a different standpoint than that of Evans-Pritchard's founding texts, taking into account aspects of social interconnection across the wider region of the southern Sudan and the longer term as well as postcolonial social history

of North East Africa as a whole and its ongoing struggles (for example, Johnson, 1994; Hutchinson, 1996). *The Nuer*, along with the collection on *African Political Systems*, coedited with Meyer Fortes and appearing in the same year, nevertheless marked the birth of the subdiscipline of field-based political anthropology and a new dialog with the growing subject of political science.

The final volume in Evans-Pritchard's trilogy devoted to the Nuer also helped create a subdiscipline, in this case the ethnographic study of religion, and also established a new baseline for interdisciplinary conversations extending as far as theology. *Nuer Religion* (1956) was written quite provocatively as a challenge to academic theology, requiring its specialists as well as a wider readership in religious studies to take tribal systems of belief and practice seriously. Evans-Pritchard's presentation of Nuer trust in *kwoth*, the Spirit of the above, has the schematic character of a creed, but at the same time offers a glimpse of a lived and shared reality. Nuer religion is certainly presented for us in terms which Evans-Pritchard has drawn, deliberately, from the traditions of Judaism and the Christian church: we are confronted not only with a 'high god' in the Nuer world, but with sin, with prayer, with souls, priests, and prophets. He portrays for us in a distinctly biblical tone, an elemental confrontation between God and Man, demanding recognition across the gulf between the historical religions and their sacred texts on the one hand and the worlds they often denigrate on the other as erring paganism or blind custom. But the analysis is not merely of belief in or representation of the divine. It focuses equally on practice; for example, upon the ritual of sacrifice in its context of bringing formerly feuding groups together, in reconciliation with each other and with the various forces of spirit. The work is presented essentially as social, rather than theological, analysis. It emphasizes how diversity of perception and representation reflects the relativity of points of view within Nuer society as established in his first book, and it draws the line (explicitly) at entering the subjectivity of religious experience. A turn toward this very subjectivity, nevertheless, has been at the heart of more recent work in the anthropology of religion, opening up avenues to a more direct exploration of experience and faith within the broad extent of the major world religions.

While Evans-Pritchard's best-known ethnographic work was carried out in the southern Sudan in the late 1920s and 1930s, he also found opportunities to undertake field research in several other countries after the outbreak of the War. He was commissioned in the Sudan Defence Force in 1940, and fought alongside locally recruited militia from the Anuak, whose people straddled the border with Ethiopia. He drew attention in early publications to the context of kingship among the Anuak, and – on the basis of passing acquaintance and historical sources rather than dedicated fieldwork – he was to later to publish what became a classic account of the related 'divine kingship' among the Shilluk (the Frazer Lecture, 1948, in Evans-Pritchard, 1962). In 1942 Evans-Pritchard was posted to Libya, where he served in the British Military Administration following the liberation of that country from Italian occupation. His investigations of the Bedouin tribes of the interior bore fruit in his book the *Sanusi of Cyrenaica* (1949), an explicitly historical treatment of some of the ideas about segmentary social relations which he had worked out for the Nuer. By the time the War was over, Evans-Pritchard had achieved a greater ethnographic range than any of his British predecessors. He had also found innovative ways of presenting his ethnography in relation to problems of a philosophical or sociopolitical kind. The combination of these qualities was the basis on which, after the War, he was able to relaunch and develop his discipline.

The Rejuvenation of Anthropology in Oxford

Back in Oxford, with his appointment as Professor of Social Anthropology in 1946, Evans-Pritchard was able initially to build on Radcliffe-Brown's work in defining and promoting 'social anthropology' and acknowledging its affiliation to the French school of Durkheim and the journal *L'Année Sociologique*. He was no more able, however, than his predecessor to establish an undergraduate degree in anthropology as such, because of the scale of sibling rivalry between interests of museum studies, biology, anatomy, sociology, and so on. So Evans-Pritchard focused on the development of 'social anthropology' as a field specifically for graduate coursework and doctoral theses almost always based on field research. He fostered a thriving community of scholars and researchers, drawn from people with a wide variety of nationalities and academic backgrounds. This diversity stimulated important new approaches and helped achieve an international profile for 'British social anthropology' in the scholarly tradition of the humanities. He facilitated studies of places and peoples in the Indian subcontinent, the Middle East, and the Mediterranean, thus opening the way for anthropology to extend its comparative scope from the 'primitive' or 'preliterate' to include studies of the social forms and cultural life of communities embedded within world's major civilizations. The Institute of Social Anthropology at Oxford trained many young anthropologists who left for distinguished careers elsewhere, including several universities in the UK, in Europe, in North America, and in the growing number of Universities in the newly independent countries of Asia and Africa (Rivière, 2007: Epilogue). Even back in the Sudan, a department of Social Anthropology & Sociology was founded in 1958 in the University of Khartoum, with Ian Cunnison as its first Professor, soon to be joined by several other anthropologists also trained in Evans-Pritchard's Institute – including Talal Asad, Lewis Hill, Ahmed al-Shahi, Peter Harries-Jones and myself. Fruitful links with anthropologists based in North America continued throughout Evans-Pritchard's years in the Oxford Chair; there were not only many American visiting scholars, but he himself spent a period in 1950 as a visiting professor at Chicago, and in 1957 as a fellow at the Center for Advanced Study in Behavioral Sciences, Stanford, California.

Although Evans-Pritchard did not embark on new field research after the War, he continued to draw on his field materials in a range of publications through his life. He also sought to define, and to some extent redefine, the historical sources of key ideas and methods in modern social anthropology. He lost no time in promoting a series of translations of essays from the French journal *L'Année Sociologique*, by Durkheim, Mauss, Hertz, Hubert, and their colleagues. Some of these translations have become established classics

worldwide – for example, Marcel Mauss's essay on *The Gift* (first translation 1954), which remains a foundation text in the teaching of anthropology, especially economic anthropology. The French connection continued – Oxford gave a lively reception to the ideas of Claude Lévi-Strauss, and indeed a warm welcome to the lecture he delivered on the occasion of his award of a honorary degree, in the early 1960s.

Evans-Pritchard was also engaged, throughout his post-War career, in a long series of comparative, thematic, and historical studies, which, by looking back to authors of the French and Scottish Enlightenment traditions, helped shape the emerging profile of the discipline of social anthropology as he understood it. It remains true that his concrete ethnographic analyses contain and exemplify his real genius, and to appreciate his 'theories' or 'methods' we need, indeed, to engage with these. But in his later writings he made explicit his life-long sympathy for the historian's perspective and his ambition to establish social anthropology as 'a kind of historiography', a comparative study of the forms of social life, which did not caricature those forms as mere empirical data but recognized their moral character and their participation in the same historical world as that of the observer (1951b, 1962). He specifically evoked R.G. Collingwood's vision of what 'history' could be (Collingwood, 1946) in sketching his own ambitions for social anthropology, and also followed Collingwood's example in drawing up a new academic lineage for his disciplinary field as he saw it. The genealogy he sketched out for social anthropology no doubt owed something to his admiration for the work of Isaiah Berlin, whom he knew well through their common membership of All Souls College. From a collection of little-known and unpublished lectures and writings by Evans-Pritchard edited and brought out posthumously by André Singer (1981), we can see, for example, the continuing lines of sympathetic thought on the nature of human social life identified on the French side from Montesquieu (1689–1775) through Condorcet (1743–94) to Comte (1798–1857 – acknowledged father of sociology) and Lévy-Bruhl – who enters our own era of twentieth century anthropological debate and overlaps with the school of Durkheim. On the Scottish side we start with Lord Kames (1696–1782), and continue with Ferguson, Millar, McLennan, Robertson Smith, and so again to the lively debates of the late nineteenth and early twentieth centuries. Evans-Pritchard took the writings of all these, along with those of writers already acknowledged as anthropology's ancestors (such as Tylor, Frazer, etc.) seriously and pinpointed some of their real insights. As a minor but charming example: he notes that in the late eighteenth century Condorcet 'supported all the liberal programs of his time', and was a believer in the perfectibility of man. All peoples about whom we know, suggested Condorcet, "fall somewhere between our present degree of civilization and what we are told about savage tribes". His work amounted to a history of human thought (Evans-Pritchard, 1981: p. 35).

It has sometimes been suggested that Evans-Pritchard's style of anthropology could be glossed as 'the translation of culture', and indeed this was adopted as the title of one of the main volumes of essays offered to him on his retirement in 1970 (Beidelman, 1971). However, as a gloss on his overall repositioning of anthropology this phrase does not really fit the bill – deriving more from late twentieth century ideas of 'culture' difference than from the disciplined comparison of social forms toward which Evans-Pritchard strove. Mauss's essay on *The Gift*, for example, is clearly about more than the 'translation of culture'. Evans-Pritchard was certainly concerned with translation, but essentially as a craftsman in handling the subtleties of language as such, as for example in his elegant paper on *sanza*, the way in which Azande employ proverbs in double-talk (1962), or in his treatments of poetry and oral literature. From his early training in history, Evans-Pritchard remained always sensitive to language, not so much as a part of 'culture', but as integral to the independent intellectual, political, and aesthetic agency, which he saw as key to the life of the peoples he studied. A project he undertook with colleagues in the 1960s was the launching of the Oxford Library of African Literature, a series that flourished over the following two decades, and had considerable influence in developing anthropology's openness to art, performance, narrative, and the multiple uses of both written and oral textual material. Several distinguished African authors were included in the series, which had significant impact beyond academia in the narrow sense.

In a very few years from his 1946 appointment, Evans-Pritchard had become something of a living legend, a 'household name' in anthropology. His works not only helped to define his subject to successive generations of students, both within anthropology and in sister disciplines. He and his colleagues also pursued a campaign for its public recognition, through radio talks (1951b), addresses to bodies such as the Fawcett Society, and reviews in journals such as the *Times Literary Supplement* and *The Listener*.

In achieving the particular success of social anthropology in Oxford, Evans-Pritchard initially had to create some distance between his approach and that of competing claims over resources, recognized posts, and approved degrees from three other interested parties – at least in Oxford – from the museum side, where ethnology was at first taught quite independently; the physical anthropology side, which had its own posts and courses; and from Sociology, which posed a new threat to the Chair of Social Anthropology, campaigning actively to take it over. The volume edited by Rivière to mark the centenary of Oxford's anthropology (2007) provides a new set of perspectives on the whole period. With hindsight one can admire the success of Evans-Pritchard in defending the 'new' social anthropology of his day, particularly in forging a clear identity in respect of sociology, which in its new post-War vigor was seen as a richer cousin and tremendous rival (and indeed still is, especially in claims to public funding). Here, his emphasis lay on anthropology's qualitative appreciation of *relational structures and processes* in social life. He pressed for us to make the widest possible use of worldwide ethnography, in part as a way of looking critically at modern-day Western social life. Anthropologists found themselves trying to explain, in a way that was not common in sociology at that time, the principles behind the uses of language in the making of persons and in meaningful interaction; as well those behind the choreography of kinship and marriage, the beliefs and rituals of religion, or even the likely hidden agendas behind the workings of authority, power, and political game-playing outside the modern nation-state.

Legacy

The lasting significance of Evans-Pritchard's lifework lies partly in its successful move away from simple observer's empiricism and a narrowly based definition of the subject matter of anthropology, toward an engagement with key debates in history, politics, literary criticism, philosophy, theology, and religious studies (for evaluations, see, for example, Douglas, 1980; Gellner, 1981, Barnes, 1987; James, 2007). At the same time, these subjects have come increasingly to recognize the value of empirical inquiry into the lives, opinions, memories, and practices of people living 'in the world', while the feminist critique and new fields such as gender studies, cultural, and media studies have adopted many ideas from anthropology. They have also helped to give a new lease of life to the idea of 'ethnography' as a reflexive engagement with the world.

Anthropology has moved definitively from the 'tribal periphery' toward the comparative study of the major civilizations, including the practice of the world religions; it is now tackling modern economic ideas and international development, urban life, and global processes. A generation of anthropologists born long after Evans-Pritchard's era have naturally sought to refashion and refresh the subject in the fast-changing world from the late twentieth into the present century, and various lines of criticism have been directed toward his work. Along with his contemporaries, he has been taken to task for not keeping more of an intellectual distance from the colonial situation in which anthropology had such a privileged position. He has been criticized for being too impressionistic in his ethnographic portrayals, for not adopting a more differentiated view of the peoples he was studying, and not attending more carefully to the specifics of their lives. He has been accused of using a patronizing tone and perpetuating character stereotypes. On the question of religion, he has been accused of presenting Nuer beliefs as too biblical and the people as too pious. He has also had his fair share of accusations over 'male bias'. Details of his Nuer ethnography (though rarely of his accounts of the Azande) have been combed over and reanalyzed in order to support various more 'rigorous' accounts based on modern social or psychological theories. Evans-Pritchard himself rarely responded directly to such criticisms. From the mid-1960s on, in common with others whose lives had become involved in the Sudan in one way or another, he was shocked and angry about the deepening civil war in the country and its effect on people he remembered, and who remembered him. Perhaps partly because of this he had no taste for picking over his earlier writings. He developed various enthusiasms for both radical and conservative causes, and seemed to enjoy his growing reputation for eccentricity (see Lienhardt's memoir, 1974). Age added more of a waspish tone to his famous wit and camaraderie, while the debates over his work were left to others.

With hindsight, and the turn of another century, it can be seen that Evans-Pritchard's work remains a source of inspiration despite the broadside against 'functionalism' and imperial collusion. He was 'accused' of working for the Sudan government, but at the time he was aware of the contradictions of his position and engaged in debate with the colonial authorities (Johnson, 1982). He put very vividly those paradoxes of multiple belonging or 'positionality', which the modern student ponders, focusing in a still helpful way on the relativity of 'self and other' in the making of personal and group identities, as we might rephrase the relevance of segmentary theory today. He placed 'dialogue' both between the Azande themselves and between himself and his informants firmly at the heart of the analysis of knowledge and belief that he carried out among them. He also respected, explicitly, the privacy and inner religious consciousness of the Nuer whose world became in so many other ways a public property through his work. It is clearly true that in many respects Evans-Pritchard failed to take 'colonialism' into account in his analyses, or to allow for historical change; but then again, looking back, he is foremost among those who worked to reorient anthropology toward history. His treatment of field research was never as an end in itself; field research was only one of many methods, including many of those scholarly methods standard to history and the social sciences, to be drawn into anthropological analysis.

Moreover, Evans-Pritchard's anthropology was broader, in practice, than many imagine, including, for example, the sensitive use of informants' own accounts about relations between men and women among the Azande – long before gender or sexuality had become an academic topic (1974). Nor was he confined to work in 'social' anthropology alone; he made quite extensive collections of ethnographic objects, musical recordings, and photographs, most now deposited in the Pitt Rivers Museum in Oxford, and available online. In Britain, social anthropology has sought to reestablish debates with the study of material culture, art, and music on the museum side and also with medical and biological anthropology. Evans-Pritchard's work remains a source of questions relevant to these new debates. By the late twentieth century, Evans-Pritchard's vision of the translatability of language, culture, and experience had come to be widely accepted as a starting point for anthropology, together with a holistic view of 'sociality' as an essentially shared human trait. Today we might claim that the 'social anthropology', which Evans-Pritchard promoted as distinct from the museum studies, or biological and evolutionary studies of his day, is now able to engage at a sensitive level with advanced modern work in these areas, and help foster new kinds of integration across the anthropological field. The structure of research and teaching in his own former Institute has since 1990 brought together a range of different specialist graduate courses within the overall institution of the 'School of Anthropology and Museum Studies', between which there is much exchange and collaboration. There are also interdisciplinary undergraduate degrees in which the legacy of 'social anthropology' is prominent and makes a constructive contribution to conversations with the new biological sciences of humanity and today's lively work of the archaeologists.

Evans-Pritchard was celebrated with several volumes in his honor during his lifetime, and with others dedicated to his memory. A research fellowship in the name of his wife, Ioma Evans-Pritchard, is established at St. Anne's College in Oxford, and All Souls College holds an annual series of Evans-Pritchard lectures primarily designed for young scholars to present their research on aspects of the anthropology, archaeology, or history of the major regions in which Evans-Pritchard himself worked: Africa, the Middle East, and the Mediterranean.

Event History Analysis

Richard J Cook and Jerald F Lawless, University of Waterloo, Waterloo, ON, Canada

Abstract

Methods for event history analysis are well suited to the study of dynamic phenomena in social and behavioral research. In such cases, stochastic models for times to events, recurrent events, or multistate transitions are often used to provide insight into the factors influencing event occurrence or changes in behavior. Intensity functions play a central role in model formulation and accommodate the study of time trends, fixed and time-varying covariates, and the study of local dependence between two or more processes of interest. Complications due to unexplained heterogeneity between individuals, incomplete observation, and other factors are discussed.

Introduction to Event History Analysis

An Overview

Event history analysis deals with the modeling and analysis of events and related phenomena that occur within individuals, populations, or systems over time. For simplicity, we consider settings in which individuals are at risk of different types of events, but the units observed could equally well be population subgroups or systems.

Methods for event history analysis have a diverse range of application within the behavioral and social sciences, involving topics such as fertility, education, employment, cohabitation and marriage, voting, addiction, and utilization of social services. Broad objectives of analysis include (1) understanding and characterizing processes governing event occurrence in individuals, (2) characterizing variability across individuals and relating it to individual characteristics, interventions, or other factors, and (3) assessing the relationship of time-varying factors or processes to the events of interest. For example, in studies of women's fertility, we might want to relate events such as pregnancy to their age, educational status, employment history, and history of cohabitation and marriage.

Subareas that fall within the domain of event history analysis follow, along with two illustrative settings in which event history methods are useful.

Survival analysis, which deals with times to a specific event, or equivalent durations of a specific condition (Kalbfleisch and Prentice, 2002; Lawless, 2003).

Recurrent event analysis, which deals with events that can occur repeatedly over time (Cook and Lawless, 2007).

Analysis of multiple events, which is concerned with the simultaneous analysis of different types of events (Cook and Lawless, 2007; Wei et al., 1989).

Transitional multistate analysis, which deals with settings where individuals occupy and move between specified states over time (Andersen and Keiding, 2002).

Example 1: Recidivism Among Criminal Offenders

Factors associated with recidivism, that is, repeated criminal acts or convictions, are of interest in connection with crime prevention and rehabilitation of offenders. This is often studied using techniques of survival or event history analysis, since charges and convictions are potentially repeatable events. For example, analysis of recidivism among juvenile offenders would consider demographic factors such as age, gender, and family, along with previous experience with the justice system (e.g., numbers of prior convictions, types of penalties imposed). This would typically involve multivariate event history methods, since there are different types of offenses and many possible outcomes to a criminal proceeding. Techniques for survival analysis are often used to fit relevant models; for example, Skardhamer and Telle (2012) consider the effects of postrelease employment on times to recidivism in Norway.

Example 2: Childbearing and Employment Among Women

Many questions are of interest concerning patterns of employment among women following childbirth. For example, are they likely to return to work part-time, or to delay reentry to their previous field of employment? Are they likely to move to self-employment? Such issues can be addressed using multistate models with different states of employment. The effects of various factors on transitions between states and on state sojourn durations can be considered: factors of interest include education, previous employment history and income, marital status, spousal employment, and previous births.

We next introduce some notation for event history models and then consider some particular types of analysis.

Notation and Key Functions

The types of events mentioned in the previous section can all be considered within the broad statistical framework of multivariate counting processes (Andersen et al., 1993). In particular, suppose J types of events are of interest and that events for a generic individual occur randomly over time. Let $N_j(t)$ denote the number of type j events ($j = 1, \ldots, J$) that occur over the time interval $(0, t)$. The stochastic process $\{N_1(s), \ldots, N_J(s), 0 < s\}$ is referred to as a multivariate counting process and the history of event occurrence up to time t^- is denoted $H(t) = \{N_1(s), \ldots, N_J(s), 0 < s < t\}$ and represents the data on events up to that time. This framework covers single, recurrent, or multiple events; multistate processes are also covered since it is possible to view different types of state-to-state transitions as different

types of events. In the multistate settings we often use additional notation: we assume there is a given set of K states $\{1, \ldots, K\}$ and let $Z(t)$ denote the state occupied at time t.

Let $\Delta N_j(t) = N_j((t+\Delta t)^-) - N_j(t^-)$ denote the number of events of type j over the time interval $[t, t+\Delta t)$. The intensity function for a type j event is defined as

$$\lambda_j(t|H(t)) = \lim_{\Delta t \downarrow 0} \frac{P\left(\Delta N_j(t) = 1 \middle| H(t)\right)}{\Delta t} \qquad [1]$$

(Andersen et al., 1993; Cook and Lawless, 2007). Under mild conditions that exclude the occurrence of more than one event at any given time and the occurrence of arbitrarily large numbers of events in a finite window of time, intensity functions fully specify the multivariate event process and hence offer a useful framework for modeling. The key challenge in event history analysis is often to understand the nature of these intensities, and to approximate them with specific mathematical forms. In most situations event occurrence may be affected by fixed or time-varying covariates, denoted $x(s)$, and in such cases we include their values up to time t in the history and let $H(t) = \{N_1(s), \ldots, N_J(s), 0 < s < t; x(s), 0 < s \leq t\}$.

The intensity functions [1] are typically the focus of attention when we want to understand the dynamics of event occurrence and features such as temporal effects or relationships between different events. In some contexts, however, we may wish to make simple summaries of data and comparisons between different types of individuals on the basis of these. In this case, it is appealing to consider marginal features of event processes. Two such features are:

(a) mean functions, $\mu(t) = E\{N(t)\}$ or corresponding rate functions, $\rho(t) = \mathrm{d}\mu(t)/\mathrm{d}t$ for recurrent events; and
(b) prevalence functions, $P_k(t) = P(Z(t) = k)$ for multistate models.

Note that in the case of a single survival time variable T, we can consider failure (death) as the sole type of event, in which case $\mu(t)$ in (a) is the distribution function for T. Equivalently, if we view the survival setting as a model with the two states: alive (1) and dead (2), then the distribution function corresponds to the prevalence function $P_2(t)$ in (b). Estimation of marginal characteristics requires fewer modeling assumptions than are required for intensity-based analyses, and marginal methods are widely used in randomized studies where simple comparisons between different groups are desired. Challenges in using marginal characteristics can arise, however, as we mention in Section Further Remarks.

Books on stochastic processes give many types of models for recurrent events (e.g., Daley and Vere-Jones, 2007; Grandell, 1997) and multistate processes (e.g., Cox and Miller, 1977; Ross, 2006). Markov processes, for which intensities [1] are functions only of the elapsed time t since the initiation of the process, and semi-Markov (or Markov renewal) processes, for which they are functions of the elapsed time since the most recent event, are mathematically tractable and widely studied. They are useful in many settings but models that allow other types of dependency on the process history are often needed. We turn now to the analysis of specific types of event history data, beginning with recurrent events. We focus on model fitting and related inference; discussions of model checking can be found in the cited references.

Analysis of Recurrent Events

Consider a recurrent event with counting process $\{N(s), 0 \leq s\}$ and intensity function $\lambda(t|H(t))$. We remark that the time origin $t = 0$ is part of the model, and in some settings there may be appealing alternative choices. In any case, suppose an individual is observed over a specified time interval (t_0, τ) and let $Y(u) = I(t_0 < u \leq \tau)$, where $I(\cdot)$ is an indicator function such that $I(A) = 1$, if A is true and equals zero otherwise. The probability density for the occurrence of n events over (t_0, τ) at times $t_1 < \cdots < t_n$ is then (Cook and Lawless, 2007; Sec. 2.1),

$$\prod_{\ell=1}^{n} \lambda(t_\ell|H(t_{\ell-1})) \cdot \exp\left(-\int_0^\infty Y(u)\lambda(u|H(u))\mathrm{d}u\right), \qquad [2]$$

which can be rewritten as

$$\prod_{\ell=1}^{n} \left\{ \lambda(t_\ell|H(t_{\ell-1})) \exp\left(-\int_{t_{\ell-1}}^{t_\ell} \lambda(u|H(u))du\right)\right\} \cdot \exp\left(-\int_{t_n}^{\tau} \lambda(u|H(u))du\right).$$

We note that the first n terms in the product above have the same form as a likelihood contribution from a survival model with 'hazard function' $\lambda(t|H(t))$ based on failure times that are left-truncated at $t_{\ell-1}$, $\ell = 1, 2, \ldots, n$ respectively; the final term corresponds to a time which is left-truncated at t_n and right-censored at τ. As a consequence of this connection, software for survival analysis can be exploited to fit many recurrent event models. In particular, if $x(t)$ is a $p \times 1$ vector of fixed covariates, time-varying covariates, or aspects of previous event history, then modulated Markov models of the Cox (1972) form are widely applicable. These specify the intensity as

$$\lambda(t|H(t)) = \lambda_0(t)\exp(x'(t)\beta), \qquad [3]$$

where β is a $p \times 1$ vector of regression coefficients. Software for fitting Cox models, such as the coxph function in R (R Development Core Team, 2011) or S-Plus (TIBCO Spotfire S+®, 2008) or PROC PHREG in SAS (SAS Institute Inc., 2008), can be used to conduct analysis; Therneau and Grambsch (2000, Chapter 8) and Cook and Lawless (2007, Chapter 3) provide details and illustrations. Cook and Lawless (2007, Chapter 4) also show how modulated semi-Markov models, for which $\lambda_0(t)$ in [3] is replaced by $\lambda_0(t - t_{N(t^-)})$, can similarly be handled, where $t - t_{N(t^-)}$ is the time elapsed since the most recent event. In each case the likelihood is assumed to be a product of terms of the form [2] across independent individuals, and the data frame on which analysis is based includes one line for each period that each individual is at risk of an event; individuals may therefore contribute several lines to the data frame (Therneau and Grambsch, 2000).

Several additional points deserve mention. First, likelihood methods remain valid when the start (t_0) and stop (τ) times of observation for each individual are random and depend on prior (but not future) process history (Aalen and Husebye, 1991). Second, the process history $H(t_0)$ prior to the start of follow-up is needed in order to specify the intensity function for some models. Third, it is assumed here that full observation of event occurrence times and covariates is possible; cases

where some information may be missing require special treatment (e.g., Lawless and Zhan, 1998; Cook and Lawless, 2007, Chapter 7; Sun and Zhao, 2013).

The model [3] can also be used to provide analysis of mean and rate functions, as defined in the Introduction. Suppose that only fixed covariates x are considered in [3] and that the form of $\lambda_0(t)$ is left unspecified. It is then known as the Andersen–Gill model (Andersen and Gill, 1982) and the rate and mean functions for an individual with covariate vector x are, respectively,

$$\rho(t|x) = \lambda_0(t)\exp(x'\beta), \quad \mu(t|x) = \Lambda_0(t)\exp(x'\beta), \qquad [4]$$

where $\Lambda_0(t) = \int_0^t \lambda_0(u)\mathrm{d}u$. These are log-linear models, which are widely used for the analysis of event counts over prespecified time intervals (McCullagh and Nelder, 1989). With a sample of m independent individuals in which the counting process $\{N_i(s), 0 < s\}$ for individual i is observed over (t_{i0}, τ_i), we let $\mathrm{d}N_i(s) = 1$ if an event occurs at time s and 0 otherwise, $Y_i(s) = I(t_{i0} < u \le \tau_i)$, and the covariate vector be x_i. Then, the estimate of the cumulative baseline intensity is

$$\widehat{\Lambda}_0(t) = \int_0^t \mathrm{d}\widehat{\Lambda}_0(s) = \sum_{s_r \in D(t)} \mathrm{d}\widehat{\Lambda}_0(s_r) \qquad [5]$$

where $D(t)$ is the set of unique event times in the sample at or before t,

$$\mathrm{d}\widehat{\Lambda}_0(s) = \frac{\sum_{i=1}^m Y_i(s)\mathrm{d}N_i(s)}{\sum_{i=1}^m Y_i(s)\exp\left(x_i'\widehat{\beta}\right)}, \qquad [6]$$

and $\widehat{\beta}$ is the estimate obtained from Cox model software, as discussed above. The estimates for β and $\Lambda_0(t)$ obtained using software for Cox regression are robust provided the multiplicative form in [4] is valid, and coxph and PROC PHREG have options that yield robust variance estimates to ensure valid inference when the Andersen–Gill (Poisson) model does not hold, but [4] does; see Cook and Lawless (2007; Sec. 3.6 and 7.2). In the absence of covariates (i.e., in a one-sample problem), the denominator in [6] simplifies to $\sum_{i=1}^m Y_i(s)$ and the resulting estimator in [5] is called the Nelson–Aalen estimator of the common mean function (Cook and Lawless, 2007). More generally, $\widehat{\Lambda}_0(t)\exp(x'\widehat{\beta})$ is an estimate of the mean function in [4]. In some situations, there is more heterogeneity (variability) in event occurrence across individuals than is accounted for by observed covariates. Sometimes this is due to inadequate incorporation of previous event history in models for the intensity, but it may also be due to unobserved factors that affect event occurrence. For the latter case, it can sometimes be helpful to introduce latent variables to represent unmeasured characteristics and use them to accommodate unexplained variation between individuals. For example, if u_i is a random effect associated with individual i, then the conditional intensity specification

$$\lambda_i(t|H_i(t), u_i) = u_i\lambda_0(t)\exp\left(x_i'(t)\beta\right) \qquad [7]$$

is often used, with the u_i assumed to be independent and identically distributed with some distribution $G(u)$. Such models are often termed 'frailty' models and can be fitted with the R/S-Plus coxph function; see Therneau and Grambsch (2000, Chapter 9) or Cook and Lawless (2007; Sec. 3.6) for details. It should be noted that all random effect models that can be fitted with existing software assume random effects for a given individual are fixed over time; this is a strong assumption.

Heterogeneity and dependence on past events cannot be clearly distinguished in many contexts. For example, suppose that u_i in [7] has a gamma distribution with $E(u) = 1$ and $var(u) = \phi$. The 'observable' intensity obtained by averaging over u_i is then (Cook and Lawless, 2007; Sec. 2.2.3)

$$\lambda(t|H_i(t)) = \left\{\frac{1 + \phi N_i(t^-)}{1 + \phi\Lambda_0(t)\exp\left(x_i'\beta\right)}\right\}\lambda_0(t)\exp\left(x_i'\beta\right) \qquad [8]$$

where for simplicity we restrict attention to the case of fixed covariates. It is apparent from [8] that the occurrence of an event leads to an instantaneous rise in the risk of subsequent event occurrence over the baseline rate $\lambda_0(t)$, and that this decreases as $t - t_{i,\,Ni(t^-)}$ increases. Note that [7] is mathematically equivalent to [8] plus the gamma assumption for u_i, and the only way we can know whether [8] arises from heterogeneity or from a direct effect of the number of previous events is through external information regarding the process (Cook and Lawless, 2013).

Multitype Recurrent Events

When recurrent events are classified into types, as discussed in Section Introduction to Event History Analysis, questions may be directed at marginal type-specific processes or at the nature of association between event types. Intensity models based on [1] and joint data on all types of events give likelihoods of the form

$$L \propto \prod_{j=1}^{J}\left\{\left[\prod_{t_{jr}\in D_j}\lambda_j\left(t_{jr}|H\left(t_{jr}\right)\right)\right]\exp\left(-\int_0^\infty Y(u)\lambda_j(u|H(u))du\right)\right\}, \qquad [9]$$

where $D_j = \{t_{jr}, r = 1, 2, \ldots, N_j(\tau)\}$ is the set of times of type j events occurring over (t_0, τ), $j = 1, 2, \ldots, J$. Provided the intensities for the different events do not share any parameters, the J different contributions to [9] can be maximized separately.

It is important to note that the likelihood [9] is based on intensities for each type of event conditioning on the prior history of all event types; using it is different than conducting independent analyses of each type. If $J = 2$, for example, intensities of the form

$$\lambda_j(t|H(t)) = \lambda_{j0}(t)\exp\left(x'(t)\beta_j + N_{3-j}(t)\theta_j\right) \quad j = 1, 2 \qquad [10]$$

may be specified, in which case $\exp(\theta_j)$ quantifies how the risk of a type j event changes with the occurrence of a type $3 - j$ event; if $\theta_1 = \theta_2 = 0$, then the two event processes are independent. An appealing feature of this formulation is that it allows one to explore asymmetric forms of so-called local dependence (Aalen et al., 2008) since we may have, for example, $\theta_1 = 0$ but $\theta_2 > 0$. In that case the occurrence of a type 2 event does not alter the risk of type 1 event, but type 1 events increase the instantaneous risk of a type 2 event.

When interest lies in examining covariate effects on separate event types, marginal models are often useful and are formed

without conditioning on the history of the other event types. That is, we consider separate models

$$\lambda_j^m\left(t\middle|H_j(t)\right) = \lim_{\Delta t\downarrow 0}\frac{P\left(\Delta N_j(t) = 1\middle|H_j(t)\right)}{\Delta t} \qquad [11]$$

where $H_j(t) = \{N_j(s), 0 < s < t; x(s), 0 < s \leq t\}$, and estimate the parameters by maximizing [9] with [11] in place of $\lambda_j(t|H(t))$. Simultaneous inferences about different types can be valid in some settings, provided robust covariance estimates are used (Cook and Lawless, 2007; Lin et al., 2000).

Another common approach for addressing dependence between event types is to assume independence between processes conditional on a shared random effect. In this case it is common to specify models similar to [7], of the form

$$\lambda_j(t|H(t),u) = \lim_{\Delta t\downarrow 0}\frac{P\left(\Delta N_j(t) = 1\middle|H(t),u\right)}{\Delta t} = u\lambda_j^m\left(t\middle|H_j(t)\right),$$

where u is a latent variable with $E(u) = 1$ and $var(u) = \phi$. If covariates are fixed, the processes are Poisson given the random effect (i.e., $\lambda_j^m(t|H_j(t)) = \rho_j(t|x)$) and if, in addition, u is gamma distributed, then in the case $J = 2$ the observed intensity for type j events becomes

$$\lambda_j(t|H(t)) = \left\{\frac{1+\phi\left[N_1\left(t^-\right)+N_2\left(t^-\right)\right]}{1+\phi[\mu_1(t|x)+\mu_2(t|x)]}\right\}\rho_j(t|x), \qquad [12]$$

where $\mu_j(t|x) = \int_0^t \rho_j(u|x)\mathrm{d}u$ is the mean function and $\rho_j(t|x)$ is the rate function for type j events, $j = 1,2$. This model extends [8] to allow the risk of type 2 events to depend on the cumulative number of type 1 events and since $\phi > 0$, it is geared toward accommodating positive associations. A limitation, however, is that this model may not adequately distinguish the effect of an event of the same type and of a complementary type. We also remark that the proportional increase in risk resulting from event occurrence in [10] is constant until the occurrence of the next event, whereas the increase in [12] is transitory.

A more general model that allows both positive and negative associations involves the specification $\lambda_j(t|H(t), u_j) = u_j\rho_j(t|x)$, where $u = (u_1,u_2)'$ follows a bivariate distribution with $E(u_j) = 1$, $var(u_j) = \phi_j$, $j = 1, 2$, and $cov(u_1,u_2) = \phi_{12}$. If $\mu(s,t) = \mu(t) - \mu(s)$, a consequence of this formulation is that $\mathrm{var}\{N_j(s,t)|x\} = \mu_j(s,t) + \mu_j^2(s,t)\phi_j$, $cov\{N_j(s_1, t_1), N_j(s_2, t_2)|x\} = \phi_j\mu_j(s_1, t_1)\,\mu_j(s_2, t_2)$, $j = 1, 2$, and $cov\{N_1(s_1, t_1), N_2(s_2, t_2)|x\} = \phi_{12}\mu_1(s_1, t_1)\,\mu_2(s_2, t_2)$, where $s_1 < t_1 < s_2 < t_2$. Thus, the separate parameters ϕ_1 and ϕ_2 accommodate heterogeneity and history dependence for the marginal processes, and a third parameter ϕ_{12} governs the association between processes. Much attention has been given to bivariate log-normal random effects distributions, but multivariate distributions based on copulas provide a richer class of models and enable the specification of different families of marginal densities for random effects (Cook et al., 2010).

Multistate Models

Dynamic processes involving distinct stages can often be conveniently represented by multistate models. As mentioned in the Introduction, such models require specification of the state space, allowable transitions, and the form of the component intensity functions. If $Z(t)$ represents which of K distinct states is occupied at time t, then $\{Z(s), 0 \leq s\}$ denotes the stochastic process. The history of the multistate process and a $p \times 1$ vector $x(t)$ of external (exogenous) covariates is denoted $H(t) = \{Z(s), 0 \leq s < t; x(s), 0 \leq s \leq t\}$. Then if $Y_k(t) = I(Z(t^-) = k)$ indicates an individual is at risk of a transition out of state k at time t,

$$\lambda_{k\ell}(t|H(t)) = \lim_{\Delta t\downarrow 0}\frac{P\left(Z\left(t+\Delta t^-\right) = \ell\middle|Y_k(t) = 1, H(t)\right)}{\Delta t}, \ell \neq k, \qquad [13]$$

denotes the intensities of $k \to \ell$ transitions. Modulated Markov models have intensities of the form

$$\lambda_{k\ell}(t|H(t)) = Y_k(t)\lambda_{k\ell}(t)\exp(x'(t)\beta_{k\ell}), \qquad [14]$$

where $\beta_{k\ell}$ is a $p \times 1$ vector of regression coefficients. The $Y_k(t)$ term in [14] is present to reflect the implicit conditioning on $Z(t^-) = k$ and that $k \to \ell$ transitions are otherwise impossible at time $t > 0$. Such models are useful when the dynamics of the process are most naturally modeled using the time since the origin of the process; examples include processes affected by aging or deterioration over time.

Modulated semi-Markov processes have intensities of the form

$$\lambda_{k\ell}(t|H(t)) = Y_k(t)h_{k\ell}(B_k(t))\exp(x'(t)\alpha_{k\ell}) \quad \ell \neq k \qquad [15]$$

where $B_k(t)$ denotes the time since entry to state k if $Y_k(t) = 1$ and $h_{k\ell}(\cdot)$ is a baseline function governing the cause-specific hazard of the sojourn time in state k ending because of a $k \to \ell$ transition. The parameters $\alpha_{k\ell}$ in [15] reflect the effect of the covariates on this transition but these have different meaning than the coefficients in [14].

If $x(t)$ is broadened to allow internal (endogenous) covariates capturing key aspects of the process history, [14] and [15] give more general intensity models. For example, if in [14] one element of $x(t)$ is $B_k(t)$, then the associated coefficient represents a duration dependence in the intensity. The simplest such model with $p = 1$ has the form $\lambda_{k\ell}(t|H(t)) = Y_k(t)\ \lambda_{k\ell}(t)\ \exp(B_k(t)\ \beta_{k\ell})$ and if $\beta_{k\ell} \neq 0$, the instantaneous risk of a $k \to \ell$ transition depends on both the time since the onset of the process and the time since state k was most recently entered. A model [15] with $p = 1$ and $x(t)$ a specified function of time has the same property with a different primary timescale. There are many options for specifying the form of the intensity functions, and intensities for different types of transitions within a given multistate process may warrant distinct forms of dependence on time.

Andersen et al. (1993) show that for multistate processes the likelihood function based on an observed set of transitions for an individual is $L \propto \prod_{k\neq\ell} L_{k\ell}$, where if $D_{k\ell}$ is the set of observed times of $k \to \ell$ transitions and $\overline{Y}_k(u) = Y(u)Y_k(u)$,

$$L_{k\ell} = \left[\prod_{t_r\in D_{k\ell}}\lambda_{k\ell}(t_r|H(t_r))\right]\exp\left(-\int_0^\infty \overline{Y}_k(u)\lambda_{k\ell}(u|H(u))du\right). \qquad [16]$$

Like [2], this has the form of a likelihood arising in survival analysis and many multistate models can be fitted with survival analysis software; see Therneau and Grambsch (2000, Sec. 8.6) and Cook and Lawless (2007; Sec. 6.7) for illustrations.

Likelihood-based methods facilitate the study of intensity-based (i.e., conditional) models for transitions and the durations of sojourns in specific states. Marginal process features are also of frequent interest and, as with recurrent events, simple estimates can be obtained for some types of models. With Markov models and fixed covariates, in particular, if $d\mathbb{A}(t|x)$ is a $K \times K$ matrix with entries $\lambda_{k\ell}(t|x)\,dt$ in the off-diagonal and $-\Sigma_{\ell \neq k}\lambda_{k\ell}(t|x)dt$ on the diagonal, and if $\mathbb{I}$ is a $K \times K$ identity matrix, then product integration (Andersen et al., 1993) gives $K \times K$ transition probability matrices for $0 \leq s \leq t$ as

$$\mathbb{P}(s,t|x) = \prod_{(s,t]}\{\mathbb{I} + d\mathbb{A}(t|x)\} \qquad [17]$$

with (k,ℓ) entry $[\mathbb{P}(s,\ t|x)]_{k\ell} = P(Z(t) = \ell|Z(s) = k, x)$. This is an important and useful result for several reasons. First, estimates of the parameters governing the transition intensities obtained by maximizing [16] can be inserted into [17] to obtain an estimate of $\mathbb{P}(s,t|x)$. Second, $\mathbb{P}(s,t|x)$ can be used to calculate estimates of marginal features such as the mean time in a given state, say ℓ, over $(0,\ \tau)$ through

$$E\left\{\int_0^\tau I(Z(u) = \ell)\mathrm{d}u\middle|x\right\} = \sum_{k=1}^{K}\int_0^\tau P(Z(u) = \ell|Z(0) = k, x)P(Z(0) = k|x)\mathrm{d}u.$$

Third, estimates of [17] can be useful in cost–benefit analyses by associating costs per unit time with each state and extending the preceding expression. In addition, such estimates are robust to departures from the Markov assumption; see Aalen et al. (2001) and Cook et al. (2009). Finally, in settings where transition times are not observed because individuals are only seen at periodic inspection times (see Section A Study in Childhood Smoking Prevention), likelihoods can be constructed based on elements in [17].

Some Illustrative Analyses

Trend in Hospital Readmission among Individuals with Affective Disorder

Kessing et al. (2004) report on a study of recurrent hospitalizations involving individuals with affective disorder. A main question of interest was whether the risk of readmission tends to increase with the number of prior admissions. The expected number of hospitalizations as a function of time since disease onset (defined as the first admission to hospital due to affective disorder) is also of interest. Here we consider data on 10 523 individuals having a discharge from a first hospitalization between 1 January 1994 and 31 December 1999. Follow-up of an individual was censored upon the diagnosis of schizophrenia, an organic disorder, or death. A total of 6498 readmissions were observed with the number of readmissions

Figure 1 Nonparametric Nelson–Aalen estimates of the cumulative intensities for readmission in the study of affective disorder, stratified by the number of prior admissions.

ranging from 0 to 89. Figure 1 gives plots of nonparametric Nelson–Aalen estimates of the cumulative Markov transition intensities for consecutive hospitalizations (see [14] and [6]), with no adjustment for covariates. Note that there is a suggestion of a trend toward increased risk of hospitalization with increasing number of prior hospitalizations; this is inferred from the increasingly steeper slopes of the cumulative transition intensities. The same feature is seen in analyses based on semi-Markov models for the readmission intensities based on [15]. The left panel of Figure 2 shows estimated baseline cumulative intensity functions in a semi-Markov model involving covariates. As discussed in the section on recurrent events, it is difficult to distinguish trends or dependence on prior events, from heterogeneity. To illustrate this point, the right panel of Figure 2 shows the corresponding estimates based on a mixed semi-Markov model with individual-level random effects; the apparent trend of increasing readmission rates is now greatly attenuated. The much more pronounced trend seen in Figure 1 and the left panel of Figure 2, thus, could be a consequence of one or more of [1] a time trend, [2] residual effects from previous hospitalizations, or [3] heterogeneity of subjects due to unobserved factors.

A Study in Childhood Smoking Prevention

To illustrate a multistate analysis based on intermittently observed subjects, we consider here a randomized youth smoking prevention study designed to evaluate the effectiveness of an experimental health promotion program on smoking behavior in children (Cameron et al., 1999). At the beginning of grade 6, 4:1 randomization was carried out with the majority of children receiving experimental intervention. Annual assessments of smoking behavior were carried out late in the year in grades 7–12. Children can be classified at any given time into one of $K = 3$ states defined as never smoked (state 1), smoker (state 2) or 'quitter' (state 3). These states are represented in Figure 3 where the arrows indicate possible transitions. Once an individual has smoked, he or she cannot subsequently qualify as 'never smoked,' so state 1 is transient, but individuals can quit and subsequently resume smoking, so $3 \rightarrow 2$ transitions are allowed.

Table 1 gives the raw counts of transitions between states over successive annual assessments. Note that while there are individuals who were in state 1 at one assessment and state 3 on the next, they are presumed to have passed through state 2 at least once and these transitions could have been made at any time between the assessments. The R package *msm* (Jackson, 2011) can be used to fit time-homogenous Markov models to data from the intervention arm and control arm separately to give insight into the dynamic aspects of the smoking process. Here we let

$$\mathbb{I} + \mathrm{d}\mathbb{A}(t) = \begin{bmatrix} 1-\lambda_{12}(t)\mathrm{d}t & \lambda_{12}(t)\mathrm{d}t & 0 \\ 0 & 1-\lambda_{23}(t)\mathrm{d}t & \lambda_{23}(t)\mathrm{d}t \\ 0 & \lambda_{32}(t)\mathrm{d}t & 1-\lambda_{32}(t)\mathrm{d}t \end{bmatrix}$$

Figure 2 Nonparametric estimates of cumulative baseline hazards from semi-Markov and mixed semi-Markov models for hospitalizations.

Figure 3 Multistate diagram for dynamic modeling of smoking behavior for analysis of the study by Cameron, R., Brown, K.S., Best, J.A., Pelkman, C.L., Madill, C.L., Manske, S.R., Payne, M.E., 1999. Effectiveness of a social influences smoking prevention program as a function of provider type, training method, and school risk. American Journal of Public Health 89, 1827–1831.

Table 1 Number of transitions between states for the smoking behavior data

		Control			*Intervention*		
To		*1*	*2*	*3*	*1*	*2*	*3*
From	1	2339	325	179	8658	1217	678

	3	0	266	372	0	907	1330

Cameron, R., Brown, K.S., Best, J.A., Pelkman, C.L., Madill, C.L., Manske, S.R., Payne, M.E., 1999. Effectiveness of a social influences smoking prevention program as a function of provider type, training method, and school risk. American Journal of Public Health 89, 1827–1831.

and obtain $\mathbb{P}(s, t)$ from [17]. If individual i is observed at assessment times $a_{i0}, a_{i1}, \ldots, a_{i,Ri}$, the likelihood for a sample of m independent individuals is

$$\prod_{i=1}^{m}\left\{\prod_{r=1}^{R_i} P\left(Z_i(a_{ir}) = z_{ir} \middle| Z_i\left(a_{i,r-1}\right) = z_{i,r-1}\right)\right\}.$$

If $\pi_k = P(Z(a_0) = k)$ governs the initial distribution, where $a_{i0} = a_0$ denotes the common baseline assessment in grade 6, a natural estimate $\widehat{\pi}_k$ is based simply on the empirical frequencies. One can then obtain

$$\widehat{P}(Z(t) = \ell) = \sum_{k=1}^{4} \widehat{P}(Z(t) = \ell | Z(a_0) = k) \cdot \widehat{\pi}_k. \qquad [18]$$

as an estimate of the prevalence for state ℓ as a function of time. These estimates of marginal state occupancy probabilities can be compared to crude estimates of the proportion of individuals in each state at each assessment time. Figure 4 shows quite good agreement between crude estimates and model-based estimates, providing some empirical validation of the Markov assumption. A time-homogeneous Markov model and a piecewise constant Markov model were fitted, where the latter adopted constant transition intensities over the elementary grades and different constant intensities during high school. The agreement with the crude prevalence estimates was noticeably better for the piecewise constant model and a likelihood ratio test of the time homogeneous assumption against this alternative leads to rejection of the null hypothesis (Control:LRS $= 112.69$, $P(\chi^2_3 > 112.69) < 0.0001$; Intervention:LRS $= 398.56$, $P(\chi^2_3 > 398.56) < 0.0001$).

Proportional intensity models of the form $\lambda_{k\ell}(t|H(t))| = \lambda_{k\ell} \exp(x'(t)\,\beta)$ were also fit to assess the effect of the intervention program and the effect of a social models risk score, which takes the value 1 for children with no parents or friends that smoke, 2 if one parent or friend smokes, and 3 if two or more parents or friends smoke. The social models risk score varies with time and was updated at each assessment when available. The results of fitting a multiplicative intensity model with the treatment indicators (Model 1) and a model with treatment and the time-dependent social models risk (Model 2) are given in Table 2.

There is no evidence of an intervention effect on the transition rates for either model. There is strong evidence, however, of the impact of the social models risk on smoking behavior. Students with a risk score of 2 have a 1.65 higher risk of starting to smoke, while children with a score of 3 have a 2.82 times higher risk. Strong reverse effects are seen on the quit rate. Interestingly, there is insignificant evidence of an effect of social models risk on resumption of smoking.

Further Remarks

Event history models are an invaluable tool in studying life history processes. When full information is available about events or states experienced by individuals in a study, survival analysis software can be employed to fit certain models. In particular, software for the Cox model allows a wide range of semiparametric models to be fitted, including those given here in [3], [7], [14], and [15]. In studies where individuals are seen intermittently, with only the states occupied at those observation times being available, analysis is more difficult. Analysis in this case is usually based on Markov models; see Cook and Lawless (2007) and for software, Jackson (2011). We have commented on the usefulness of models for marginal process features such as rate, mean, and prevalence functions. Estimates based on Markov models for recurrent events and multistate processes have certain robustness properties, provided that the length or frequency of follow-up for individuals is independent of their event processes. When this independence condition is violated, inverse probability weighting methods can be employed to adjust for event history-dependent follow-up in some cases (Cook et al., 2009). A second challenge for marginal analyses is that when processes involve 'terminal' events or states such as death, the specification of marginal event rates and mean functions is more complicated. For discussion and methodology associated with these issues, see Cook et al. (2009).

Understanding of causal relationships between time-varying factors and important lifetime events is explicitly or implicitly the goal in many fields of study. Methods for event history analysis offer a powerful framework for studying dynamic processes and causal factors that influence process dynamics. There are different schools of causal inference but given the focus on modeling phenomena as they unfold over time, event history methods are best suited to answering questions within

Figure 4 Estimated prevalences in states 1, 2, and 3 for individuals in the control (left) and intervention (right) groups based on a time-homogeneous and a two-piece Markov model fitted using the *msm* function (Jackson, C.H., 2011. Multi-state models for panel data: the msm package for R. Journal of Statistical Software 38, 1–28) and [18], with the corresponding crude estimates represented by dots; the spacing on the x-axis reflects the fact that grade 6 assessments were early in the academic year and each subsequent annual assessment took place at the end of the academic year.

the Granger–Schweder framework (Granger, 1969; Schweder, 1970); see Chapter 9 of Aalen et al. (2008) for an excellent discussion. The remarks in Section Multitype Recurrent Events on studies of local dependence through the use of intensity-based models are a brief allusion to this approach.

We have emphasized the use of intensity-based models with multiplicative covariate effects, but as in standard survival analysis, covariates may be studied on the basis of time-transform models (Cheng et al., 1995), additive models (Aalen et al., 2001), or hybrid models with additive and multiplicative effects such as the Cox–Aalen model (Martinussen and Scheike, 2006). The timereg package in R facilitates the fitting of quite general models having time-dependent covariates with time-varying effects, and this facility proves particularly helpful in problems involving causal inferences (see Aalen et al., 2008, Chapter 9).

In some situations individuals or processes may be grouped into clusters and in that case it may be important to account for intracluster association. This can be done in ways analogous to those in Section Multitype Recurrent Events, either by the introduction of cluster-specific random effects (Cook et al., 2004; Sutradhar and Cook, 2008) or by the development of robust variance estimation for marginal methods. For robust methods involving time to event data see Lee et al. (1992), for recurrent events see Cook and Lawless (2007; Sec. 8.5 and 8.9) and references therein, and for multistate models see Lee and Kim (1998). Finally, in some settings the selection or follow-up of individuals in a study may be related to their event histories. Methods for adjusting for selection effects are then needed; see Cook and Lawless (2007, Chapter 7) and Cook and Lawless (2014; Sec. 6).

Acknowledgments

This research was supported by grants from the Natural Sciences and Engineering Research Council of Canada to RJC (Grant No. 101093) and JFL (Grant No. 103167) and an operating grant from the Canadian Institutes for Health Research to RJC (Grant No. 105099). Richard Cook is Canada Research Chair in Statistical Methods for Health Research. Data on hospitalizations in affective disorder were kindly provided by Professor Lars Vedel Kessing and Professor Per Kragh Andersen who have used the data in prior publications on recurrent events. We thank Professors Steve Brown and Roy Cameron for permission to use the data from the Waterloo Smoking Prevention Project, which was funded by NHLBI (U.S.) and NHRDP (Canada). Assistance with the statistical computing from Ker-Ai Lee is also gratefully acknowledged.

Abstract

Event history analyses investigate collections of individuals or units moving between different observed states. This article discusses applications of this type of analysis. It first distinguishes different ways of collecting data, contrasting event-oriented observations. Then, it details basic terminology and the central concept of the transitional rate. In conclusion, it discusses the inclusion of time-varying covariates in transition rate models and describes three successful applications of event history analysis in different substantive contexts.

'Event history analysis' is the study of processes that are characterized in the following general way: (1) there is a collection of units (which may be individuals, organizations, societies, etc.), each moving among a finite (usually small) number of states; (2) these changes (or events) may occur at any point in time (i.e., they are not restricted to predetermined points in time); and (3) there are time-constant and/or time-varying factors influencing the timing of events. In this article, various examples of event history applications are presented, the advantages and problems of different observation plans are discussed, the terminology and central concepts of event history analysis (e.g., transition rate or censoring) are demonstrated, and practical complications of statistical models (e.g., exponential, piecewise constant, Cox, Gompertz–Makeham, Weibull, Sickle, Log-logistic, Log-normal, or Gamma model) are addressed.

'Event history analysis' studies a collection of units, each moving among a finite (usually small) number of states. An example is individuals who are moving from unemployment to employment. In this article, various examples of event history applications are presented, the concepts and advantages of event history analysis are demonstrated, and practical complications are addressed.

Examples of Continuous-Time, Discrete-State Processes

Event history analysis is the study of processes that are characterized in the following general way: (1) there is a collection of units (which may be individuals, organizations, societies, etc.), each moving among a finite (usually small) number of states; (2) these changes (or events) may occur at any point in time (i.e., they are not restricted to predetermined points in time); and (3) there are time-constant and/or time-varying factors influencing the timing of events. Examples are workers who move between unemployment and employment; men and women who enter into consensual unions or marriages; companies that are founded or closed down; governments that break down; people who are mobile between different regions or nation-states; consumers who switch from one brand to another; prisoners who are released and commit another crime; people who show certain types of verbal and nonverbal behaviors in social interactions; students who drop out of school; incidences of racial and ethnic confrontation, protest, riot, and attack; people who show signs of psychoses or neuroses; patients who switch between the states 'healthy' and 'diseased,' and so on. In event history analysis, the central characteristics of the underlying stochastic process are mirrored in the specific way theoretical and mathematical models are built, data are collected, and the estimation and evaluation of models is done.

Different Observation Plans

In event history analysis, the special importance of broader research design issues has been stressed. In particular, different observation plans have been used to collect information on the continuous-time, discrete-state substantive process. These various schemes produce different types of data that constrain the statistical analysis in different ways: cross-sectional data, event count data, event sequence data, panel data, and event history data.

The cross-sectional observation design is still the most common form of data collection in many fields. A cross-sectional sample is only a 'snapshot' taken on the continuous-time, discrete-state substantive process (e.g., the jobs of people at the time of the interview). Event history analysis has shown that one must be very cautious in drawing inferences about explanatory variables on the basis of such data, because, implicitly or explicitly, social researchers have to assume that the process under study is in some kind of equilibrium. Equilibrium means that the state probabilities are fairly trendless and the relationships among the variables are quite stable over time. Therefore, an equilibrium of the process requires that the inflows to and the outflows from each of the discrete states be equal over time to a large extent. This is a strong assumption that is not very often justified in the social and behavioral sciences (see Blossfeld and Rohwer, 1995).

A comparatively rare type of data on changes of the process are event count data (Andersen et al., 1993). They record the number of different types of events for each unit in an interval (e.g., the number of racial and ethnic confrontations, protests, riots, or attacks in a period of 10 years). Event sequence data provide even more information. They record the sequence of

specific states occupied by each unit over time (e.g., *see* Event Sequence Analysis: Methods). The temporal data most often available to the scientist are panel data. They provide information on the same units of analysis at a series of discrete points in time. In other words, there is only information on the states of the units at predetermined survey points, and the course of the process between the survey points remains unknown. Panel data certainly contain more information than cross-sectional data, but involve well-known distortions created by the method itself (e.g., panel bias, attrition of sample). In addition, causal inferences based on panel approaches are much more complicated than has been generally acknowledged (Blossfeld and Rohwer, 1995). With regard to the continuous-time, discrete-state substantive process, panel analysis is particularly sensitive to the length of the time intervals between the waves relative to the speed of the process. They can be too short, so that too few state transitions will be observed; or too long, so that it is difficult to establish a time order between the events (Allison, 2014).

The event-oriented observation design records the complete sequence of states occupied by each unit and the timing of changes among these states. For example, an event history of job mobility consists of more or less detailed information about each of the jobs and the exact beginning and ending dates of each job. Thus, this is the most complete information one can get on the continuous-time, discrete-state substantive process. Such event history data are often collected retrospectively with life history studies. Life history studies are normally cheaper than panel studies and have the advantage that they code the data into one framework of codes and meaning. But retrospective studies also suffer from several limitations (see Blossfeld and Rohwer, 1995). In particular, data concerning motivational, attitudinal, cognitive, or affective states are difficult (or even impossible) to collect retrospectively because the respondents can hardly recall the timing of changes in these states accurately. Also, the retrospective collection of behavioral data has a high potential for bias because of its strong reliance on autobiographic memory. To reduce these problems of data collection, modern panel studies (e.g., the Panel Study of Income Dynamics (PSID) in the United States, the British Household and Panel Survey (BHPS) in the UK, or the Sozio-oekonomisches Panel (SOEP) in Germany) use a mixed design, which provides traditional panel data and retrospectively collects event history data for the period before the first panel wave and between the successive panel waves.

Event History Analysis

Event history analysis, originally developed as independent applications of mathematical probability theory in demography (e.g., the classical life table analysis and the product-limit estimator of Kaplan and Meier (1958)), reliability engineering, and biostatistics (e.g., the path-breaking semiparametric regression model for survival data of David Cox (1972)) has gained increasing importance in the social and behavioral sciences (see Tuma and Hannan, 1984; Blossfeld et al., 1989; Lancaster, 1990; Andersen et al., 1993; Blossfeld and Rohwer, 1995; Broström, 2012; Blossfeld et al., 2007) since the early 1980s. Due to the development and application of these methods in various disciplines, the terminology is normally not easily accessible to the user. Central definitions are therefore given first.

Basic Terminology

Event history analysis studies transitions across a set of discrete states, including the length of time intervals between entry to and exit from specific states. The basic analytical framework is a state space and a time axis. The choice of the time axis or clock (e.g., age, experience, marriage duration, etc.) used in the analysis must be based on theoretical considerations and affects the statistical model. Dependent on practical and theoretical reasons, there are event history methods using a discrete (Yamaguchi, 1991; Vermunt, 1997) or continuous time axis (Tuma and Hannan, 1984; Blossfeld et al., 1989; Courgeau and Lelièvre, 1992; Blossfeld and Rohwer, 1995). Discrete-time event history models are, however, special cases of continuous-time models and are therefore not further discussed here. An episode, spell, waiting time, or duration – terms that are used interchangeably in the literature – is the time span a unit of analysis (e.g., an individual) spends in a specific state. The states are discrete and usually small in number. The definition of a set of possible states, called the state space, is also dependent on substantive considerations. Thus, a careful, theoretically driven choice of the time axis and design of state space are crucial, because they are often serious sources of misspecification.

The most restricted event history model is based on a process with only a single episode and two states (an origin state j and a destination state k). An example may be the duration of first marriage until the end of the marriage, for whatever reason (separation, divorce, death). In the single episode case, each unit of analysis that entered into the origin state is represented by one episode. Event history models are called multistate models, if more than one destination state exists. Models for the special case with a single origin state but two or more destination states are also called models with competing events or risks. For example, a housewife might become 'unemployed' (meaning entering into the state 'looking for work'), or start being 'full-time' or 'part-time employed.' If more than one event is possible (i.e., if there are repeated events or transitions over the observation period), the term multiepisode model is used. For example, an employment career normally consists of a series of job shifts.

Censoring

Observations of event histories are often censored (Keiding, 2014). Censoring occurs when the information about the duration in the origin state is incompletely recorded. An episode is fully censored on the left, if starting and ending times of a spell are located before the beginning of an observation period (e.g., before the first panel wave), and it is partially censored on the left, if the length of time a unit has already spent in the origin state is unknown. This is typically the case in panel studies, if individuals' job episodes at the time of a first panel wave is known but no further information about the history of the job is collected. Left censoring is normally a difficult problem because it is not possible to take the effects

of the unknown episodes into account. It is only without problems, if the assumption of a Markov process is justified (i.e., if the transition rates do not depend on the duration in the origin state).

The usual kind of censoring, however, is right censoring. In this case, the end of the episode is not observed but the observation of the episode is terminated at an arbitrary point in time. This type of censoring typically occurs in life course studies at the time of the retrospective interviews or in panel studies at the time of the last panel wave. Because the timing of the end of the observation window is normally determined independently from the substantive process under study, this type of right censoring is unproblematic and can easily be handled with event history methods (Kalbfleisch and Prentice, 1980 – type I censoring). Finally, episodes might be completely censored on the right. In other words, entry into and exit from the duration occurs after the observation period. This type of censoring normally happens in retrospective life history studies in which individuals of various birth cohorts can only be observed over very different spans of life. To avoid sample selection bias, such models have to take into account variables controlling for the selection; for example, by including birth cohort dummy variables (see Yamaguchi, 1991).

The Transition Rate

The central concept of event history analysis is the transition rate. Because of the various origins of event history analysis in the different disciplines, the transition rate is also called the hazard rate, intensity rate, failure rate, transition intensity, risk function, or mortality rate:

$$r(t) = \lim_{t' \to t} pr(t \leq T < t' | T \geq t)/(t' - t) \qquad [1]$$

The transition rate provides a local, time-related description of how the process evolves over time. It can be interpreted as the propensity (or intensity) to change from an origin state to a destination state, at time t. But one should note that this propensity is defined in relation to a risk set ($T \geq t$) at t, i.e., the set of units that still can experience the event because they have not yet had the event before t.

Statistical Models

The central idea in event history analysis is to make the transition rate, which describes a process evolving in time, dependent on time (t) and on a set of covariates, x:

$$r(t) = g(t, x) \qquad [2]$$

The causal interpretation (*see* Explanation: Conceptions in the Social Sciences) of the transition rate requires that we take the temporal order in which the processes evolve very seriously. In other words, at any given point in time, t, the transition rate $r(t)$ can be made dependent on conditions that happened to occur in the past (i.e., before t), but not on what is the case at t or in the future, after t.

There are several possibilities to specify the functional relationship g (see Blossfeld and Rohwer, 1995). For example, the exponential model, which normally serves as a baseline model, assumes that the transition rate can vary with different constellations of covariates x, but that the rates are time-constant. The piecewise constant exponential model allows the transition rate to vary across fixed time periods with period-specific effects of covariates. There are also different parametric models, which are based on specific shapes of the time-dependence (e.g., the Gompertz-Makeham, Weibull, Sickle, Log-logistic, Log-normal, or Gamma model). If the time-shape of the baseline hazard rate is unspecified and only possible effects of covariates x are estimated, the model is called a semi-parametric or partial likelihood model (Cox, 1972). Finally, there are also models of unobserved heterogeneity in which the transition rate can be made dependent on the observed covariates x, the duration t, and a stochastic error term.

Parallel and Interdependent Processes

The most important scientific progress permitted by event history analysis is based on the opportunity to include explicitly measured time-varying covariates in transition rate models (see Blossfeld and Rohwer, 1995). These covariates can change their values over process time in an analysis. Time-varying covariates can be qualitative or quantitative, and may stay constant for finite periods of time or change continuously. From a substantive point of view, time-varying covariates can be conceptualized as observations of the sample path of parallel processes. These processes can operate at different levels. In sociology, for example, (1) there can be parallel processes at the level of the individual's different domains of life (e.g., one may ask how upward and downward moves in an individual's job career influence his/her family trajectory); (2) there may be parallel processes at the level of some few individuals interacting with each other (e.g., one might study the effect of the career of the husband on his wife's labor force participation); (3) there may be parallel processes at the intermediate level (e.g., one can analyze how organizational growth influences career advancement or changing household structure determines women's labor force participation); (4) there may be parallel processes at the macro level (e.g., one may be interested in the effect of changes in the business cycle on family formation or career advancement); and (5) there may be any combination of such processes of type (1) to (4). For example, in the study of life-course, cohort and period effects, time-dependent covariates at different levels (see below) must be included simultaneously (multilevel analysis).

In dealing with such systems of parallel processes, the issue of reverse causation is often addressed in the methodological literature (see, e.g., Kalbfleisch and Prentice, 1980; Tuma and Hannan, 1984; Blossfeld et al., 1989; Yamaguchi, 1991; Courgeau and Lelièvre, 1992). Reverse causation refers to the (direct or indirect) effect of the dependent process on the independent covariate process(es). Reverse causation is often seen as a problem because the effect of a time-dependent covariate on the transition rate is confounded with a feedback effect of the dependent process on the values of the time-dependent covariate. However, Blossfeld and Rohwer (1995) have developed a causal approach to the analysis of interdependent processes that also works in the case of interdependence, too. For example, if two interdependent processes, Y_t^A and Y_t^B, are given, a change in Y_t^A at any (specific) point in time

t' may be modeled as being depend on the history of both processes up to, but not including t'. Or stated in another way: what happens with Y_t^A at any point in time t' is conditionally independent of what happens with Y_t^B at t', conditional on the history of the joint process $Y_t = (Y_t^A, Y_t^B)$ up to, but not including, t ('principle of conditional independence'). Of course, the same reasoning can be applied if one focuses on Y_t^B instead of Y_t^A as the 'dependent variable.' Beginning with a transition rate model for the joint process, $Y_t = (Y_t^A, Y_t^B)$, and assuming the principle of conditional independence, the likelihood for this model can then be factorized into a product of the likelihoods for two separate models: a transition rate model for Y_t^A, which is dependent on Y_t^B as a time-dependent covariate, and a transition rate model for Y_t^B, which is dependent on Y_t^A as a time-dependent covariate. From a technical point of view, there is therefore no need to distinguish between defined, ancillary, and internal covariates (see, e.g., Kalbfleisch and Prentice, 1980), because all of these time-varying covariate types can be treated in the estimation procedure. Estimating the effects of time-varying processes on the transition rate can easily be achieved by applying the method of episode splitting (see Blossfeld and Rohwer, 1995).

Unobserved Heterogeneity

Unfortunately, researchers are not always able to include all the important covariates into an event history analysis. These unobserved differences between subpopulations can lead to apparent time-dependence at the population level and additional identification problems. There exists a fairly large literature on misspecified models in general. In particular, there have been several proposals to deal with unobserved heterogeneity in transition rate models (the so-called frailty models) (see, e.g., Blossfeld and Rohwer, 1995).

Illustrative Applications

The following three applications illustrate the technical strength of event history models in different substantive contexts.

A Multilevel Analysis of Life-Course, Cohort, and Period Effects in Career Mobility

Any standard statistical analysis using age, year of birth (as a cohort measure), and chronological year of measurement (as a period measure) leads to an identification problem (age = year of measurement − year of birth). The technical solution to that problem often is to assume that at least one of these measures is constant over time or to apply arbitrary statistical constraints. Blossfeld (1986) in an event history study of career mobility of German men approached this problem from a more substantive point of view. He suggested to rely more on explicit measures for the theoretically important macro effects of cohort and period and used 14 time series from official statistics indicating the long-term development of the labor market structure in Germany. Based on factor analysis, he first reduced the 14 highly correlated time series to two orthogonal macro factors, which represented the 'monotonic trend in the level of modernization' and the 'cyclic changes in labor market conditions,' and then matched these macro data to individual event career data to conduct a multilevel analysis. To represent the changing conditions under which cohorts enter the labor market, Blossfeld used the factor scores of these two factors at the year men entered the labor force. To introduce period as a time-dependent covariate, he used the method of episode splitting. In accordance with this method, the original job episodes were split into subepisodes every year so that the factor scores of the two macro factors could be updated in each job episode for all employed men every year. Modeling cohort and period effects this way not only provides more direct and valid measures of the explanatory concepts, but also results in the disappearance of the problem of nonestimable parameters above. It was, therefore, not necessary to impose (in substantive terms normally unjustifiable) constraints on the parameters to identify life-course, cohort, and period effects.

Parallel Processes at the Level of the Individual: Women's Rising Educational and Career Investments, and Changes in the Process of Family Formation

Using event history models, Blossfeld and Huinink assessed the hypothesis of the 'new home economics' that women's rising educational and career investments will lead to a decline in marriage and motherhood (see Blossfeld and Rohwer, 1995: 143). Because the accumulation of educational and career resources is a lifetime process, they analyzed it as a dynamic process over the life course. To model the changes in the accumulation of qualifications over the life course, Blossfeld and Huinink updated a time-varying covariate 'level of education' at the age when a woman obtained a particular educational rank in the hierarchy. They also generated a time-dependent dummy variable indicating whether or not a woman is attending the educational system at a specific age. Finally, for the dynamic modeling of job-specific investments in human capital over the life course, Blossfeld and Huinink have developed a specific time-dependent labor force experience measure, which they called 'career resources.' The time-dependent increments and final levels of this measure were designed to reflect the 'quality of each job' and the respective 'employment durations.' The time-dependent measure also took into account that career resources are declining when women interrupted their employment career. Blossfeld and Huinink applied the method of episode splitting to include these various time-dependent dimensions of education and career together with additional control variables in the rate equation. The results of their longitudinal analysis were surprising: contrary to the expectations of the economic approach to the family, women's entry into marriage obviously was independent of women's level of education and their career resources. Equally surprisingly, the effect of women's level of education on the rate of their first birth was even positive. An explanation for the positive effect on the timing of first birth is easily demonstrated with an event history model: women who remain in school longer and attain high qualifications are first shifting their fertility decisions to higher ages, and then, they are subject to pressure not only from the

potential increase in medical problems connected with having children late, but also from societal age norms. Thus the higher the educational attainment level, the stronger the catching-up effect. This application demonstrates that the standard empirical support for the economic theory of the family claimed on the basis of cross-sectional data might be misleading. Cross-sectional data do not permit a differentiation between the time-dependent effect of accumulation of human capital over the life course and the time-dependent effect of participation in the educational system.

A Causal Approach to Interdependent Systems: The Effects of Pregnancy on Entry into Marriage for Couples Living in Consensual Unions

Finally, the application of a causal approach to interdependent systems is demonstrated by Blossfeld and Rohwer in an analysis of the effect of pregnancy on entry into marriage in Germany (see Blossfeld and Rohwer, 1995: 157). This study shows that the effect of a fertility event on entry into marriage is highly time dependent: It starts to rise at some time shortly after conception (thus there is some time lag involved between cause and effect), increases during pregnancy to a maximum at around 7–8 months after conception, and then decreases again reaching a level even below the starting level at around 6 months after the birth of the child. Thus, the dynamic interdependence of fertility and nuptiality mainly occurs in a very specific phase of the life course and the unfolding effect of fertility on nuptiality is highly dynamic over time. Of course, standard statistical applications based on cross-sectional observation can be hardly used to analyze such situations in a meaningful way. However, in event history analysis, there is an easy way to approach that problem. One can use a series of time-dependent dummy variables each indicating a month since the occurrence of conception (the causal event). They show that the effects of the time-dependent dummy variable at first increase, reach a maximum, and then decrease again. Thus, starting with conception, there is an increasing normative pressure to avoid an illegitimate birth that increases the marriage rate, particularly for people who are already 'ready for marriage.' But with an increasing number of marriages, the composition of the group of still unmarried couples shifts toward couples being 'less ready for marriage' or being 'not ready for marriage,' which, of course, decreases the fertility effect again. This is an important result not only in substantive terms; the methodological lesson for event history analysis is also revealing. One should be very careful in modeling qualitative parallel processes with only one dummy variable (e.g., in the current application using only the time of conception, or the time of birth for the switch of the time-dependent covariate) because the effect itself might be highly time-dependent. For example, Blossfeld and Rohwer show that the fertility effect disappears completely, when the time-dependent covariate is switched at the time of birth because then a period with a low-marriage rate up to the time of discovery of conception and a period with a high-marriage rate during pregnancy is aggregated and compared with a period of low rate after the birth of the child.

Event History Analysis in Continuous Time

Per K Andersen and Niels Keiding, University of Copenhagen, Copenhagen, Denmark

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Event history data are obtained by observing individuals over time, focusing on times of occurrence of certain events and the types of event occurring. A review is given of event history analysis (in continuous time) based on multistate models. Examples of such models include the two-state model for survival data and the competing risks and disability models. The likelihood function for a multistate model is presented using the theory of counting processes with special emphasis on models with piecewise constant transition intensities, nonparametric models, and models for the transition intensities including covariates along the lines of the semiparametric Cox proportional hazards regression model for survival data. Direct models for various marginal features of event history data, such as state occupation probabilities, are also discussed. Finally, the influence of observational patterns on the inference is discussed.

Introduction

Event history analysis deals with data obtained by observing individuals over time focusing on events occurring for the individuals. Thus, typical outcome data consist of *times of occurrence* of events and of the *types of events* which occurred. Frequently, an event may be considered as a *transition* from one state to another and, therefore, *multistate models* will often provide a relevant modeling framework for event history data. Multistate models are discussed from several points of view in the books by Andersen et al. (1993), Kalbfleisch and Prentice (2002), Martinussen and Scheike (2006), Aalen et al. (2008), Blossfeld and Rohwer (1995), and Courgeau and Leliévre (1992), see also survey papers by Andersen and Keiding (2002), Andersen and Pohar Perme (2008), and Keiding (2014).

Survival Data

The simplest multistate model is the two-state model for survival data with one initial state 0: alive and one final state 1: dead, see **Figure 1**. The observation for a given individual will here in the simplest form consist of a random variable, say T, representing the time from a given origin (time 0) to the occurrence of the event death. The distribution of T may be characterized by the probability distribution function $F(t) = \text{Prob}(T \leq t)$ or, equivalently, by the survival distribution function $S(t) = 1 - F(t) = \text{Prob}(T > t)$. It is seen that $S(t)$ and $F(t)$, respectively, correspond to the probabilities of being in state 0 or 1 at time t. If every individual is assumed to be in state 0 at time 0 then $F(t)$ is also the *transition probability* from state 0 to state 1 for the time interval from 0 to t. In continuous time the distribution of T may also be characterized by the *hazard rate function*.

Figure 1 The two-state model for survival data.

$$\alpha(t) = -\mathrm{d}\log S(t)/\mathrm{d}t = \lim_{\Delta t \to 0} \frac{\text{Prob}(T \leq t + \Delta t | T \geq t)}{\Delta t}$$

that is

$$S(t) = \exp\left(-\int_0^t \alpha(u)\mathrm{d}u\right)$$

Thus, $\alpha(\cdot)$ is the *transition intensity* from state 0 to state 1, that is, the instantaneous probability per time unit of going from state 0 to state 1. The intensity of going from state 1 to state 0 is 0 and state 1 is then said to be *absorbing*, defined as a state from which further transitions cannot occur. A *transient* state is a state which is not absorbing and in this simple two-state model state 0 is transient.

In general, event history analysis deals with inference for transition intensities and transition or state occupation probabilities in multistate models. This includes estimation and hypothesis tests for these quantities and analysis of regression models where these quantities are related to (possibly time-dependent) explanatory variables observed for the individuals under study. Most frequently, multistate models are defined by their transition intensities from which transition or state occupation probabilities may be derived by plug-in or by micro-simulation. However, sometimes the main *target of inference* for event history analysis is different and, for example, direct, *marginal* models for probabilities may be studied. Examples are provided below.

A typical feature of event history analysis is the inability to observe complete event histories, for example, by the end of the observation period all individuals under study may not have reached an absorbing state. In survival analysis this would correspond to individuals still being alive by the end of the study and this kind of *incomplete observation* is known as *right-censoring*. Furthermore, all individuals may not have been observed from the same time origin. This kind of incomplete observation where individuals are only observed conditionally on not having reached an absorbing state by the time of initiation of the study is known as *left-truncation*. Restricting attention to right-censoring a crucial problem is whether the available incomplete data enables one to make valid inference

on parameters in the multistate model for the complete data. The condition for this is known as *independent* right-censoring and the interpretation is that a sample observed after independent right-censoring is representative for the population without censoring. This means that individuals who are censored should have neither lower nor higher risk of future events than individuals who are not censored (see, e.g., Andersen et al., 1993: Chapter III; Kalbfleisch and Prentice, 2002: p. 194).

Right-censoring may be caused by a number of different mechanisms. Suppose, for example, that one is interested in the disease-specific mortality for patients suffering from a given disease like skin cancer and followed from their times of diagnosis (time 0). Then right-censoring may be caused by

1. a patient still being alive by the time of closure of the study,
2. a patient being lost to follow-up,
3. a patient dying from causes other than skin cancer.

In case (1) there are usually no reasons to believe that censoring should not be independent since the time of closure of a study can most often be assumed independent of the process observed. In case (2) one may be suspicious that patients lost to follow-up could be individuals who generally feel well (or the opposite) and, therefore, do not want to take part in a study any more and this could lead to *dependent* censoring. Situation (3) is more tricky since here the population without censoring is quite hypothetical: it is hardly reasonable to think of a population of skin cancer patients for whom it is impossible to die from other causes. This fact has consequences for how to choose an appropriate model in this situation and a relevant model to consider could be a *competing risks model*, see Figure 2.

The problem is that even though it may be possible to make valid inference for the single cause-specific hazard $\alpha_1(t)$ of dying from skin cancer by using methods for survival data and treating deaths from other causes as right-censored observations then, to evaluate the survival probability for skin cancer patients, the intensity of dying from other causes is also needed. In Section Multistate Models we return to the relationship between the two cause-specific hazards and the transition probabilities in Figure 2. The conclusion is that a *partial model specification* where the hazard, $\alpha_2(t)$, of dying from other causes is not modeled may suffice for some, but not all, purposes and a multistate model like the one depicted in Figure 2 can be a sensible model to study in spite of the fact that focus may be on a single transition. Partial model specification is further discussed in Section Statistical Model Specification.

Figure 2 Competing risks model for skin cancer (s.c.) mortality (o.c., other causes).

Multistate Models

In this section, we will present a number of different multistate models including the two-state model for survival data and the competing risks model introduced in Section Survival Data. We will begin with a few definitions. Some of the definitions are formulated loosely but they may all be made rigorous within the framework of so-called *marked point processes* (Andersen et al., 1993: Chapter III; Arjas and Haara, 1984).

A multistate process is a stochastic process $(X(t), t \in \mathcal{T})$ with a finite state space $\mathcal{S} = \{1, \ldots, p\}$ and with right-continuous sample paths: $X(t+) = X(t)$. Here, $\mathcal{T} = [0, \tau]$ or $[0, \tau]$ with $\tau \leq +\infty$. The process has *initial distribution* $\pi_h(0) = \text{Prob}(X(0) = h)$, $h \in \mathcal{S}$. A multistate process $X(\cdot)$ generates a *history* $\mathcal{X}_t$ consisting of the observation of the process in the interval $[0, t]$. Relative to this history we may define *transition probabilities* by

$$P_{hj}(s,t) = \text{Prob}(X(t) = j | X(s) = h, \chi_{s-})$$

for $h, j \in \mathcal{S}$, $s, t \in \mathcal{T}$, $s \leq t$, and for $j \neq h$ *transition intensities* by the derivatives

$$\alpha_{hj}(t) = \lim_{\Delta t \to 0} P_{hj}(t, t + \Delta t)/\Delta t$$

which we shall assume exist. Some transition intensities may be 0 for all t. Graphically, multistate models may be illustrated using diagrams like Figure 1 or 2 with boxes representing the states and with arrows between the states representing the possible transitions, that is, the nonzero transition intensities (Hoem, 1976; Andersen et al., 1993: Section I.3). A state $h \in S$ is *absorbing* if for all $t \in \mathcal{T}$, $j \in \mathcal{S}$, $j \neq h$, $\alpha_{hj}(t) = 0$, otherwise h is *transient*. The *state occupation probabilities* $\pi_h(t) = \text{Prob}(X(t) = h)$ are given by

$$\pi_h(t) = \sum_{j \in \mathcal{S}} \pi_j(0) P_{jh}(0,t)$$

Notice that the $P_{hj}(\cdot,\cdot)$, the $\pi_h(\cdot)$, and the $\alpha_{hj}(\cdot)$ all depend both on the probability measure Prob and on the history. The process is *Markovian* if transition intensities $\alpha_{hj}(t)$ only depend on the history via the state $h = X(t)$ occupied at time t. Sometimes one is interested in considering an extended history which also includes observed *covariates*. If only time-fixed covariates Z are studied then the observed history is $\mathcal{F}_t = \mathcal{X}_t \vee \mathcal{Z}_0$ whereas time-dependent covariates $Z(t)$ give rise to an extended history of the form $\mathcal{F}_t = \mathcal{X}_t \vee \mathcal{Z}_t$ where in both cases $\mathcal{Z}_t$ is the history generated by the covariates in $[0, t]$. We shall here focus on the *purely endogenous* case where $\mathcal{Z}_t \subset \mathcal{X}_t \vee \mathcal{Z}_0$, that is, the covariates are either all time-fixed or the random development of the time-dependent covariates is fully specified by the history of the process itself (see, however, Section Statistical Model Specification).

The Two-State Model for Survival Data

This model, illustrated in Figure 1, has $p = 2$ states and only one possible transition from state 0 to state 1. The corresponding transition intensity $\alpha_{01}(t)$ is given by the hazard rate function $\alpha(t)$, while $\alpha_{10}(t) = 0$ for all t, that is, state 1 is absorbing. The initial distribution is degenerate in 0: $\pi_0(0) = 1$ and the process is Markovian. Covariates may be entered into the model using a regression model for $\alpha(\cdot)$.

The Competing Risks Model

This model has one transient state 0: alive and a number, k, of absorbing states, state h, $h = 1,\ldots, k$ corresponding to death from cause h. Thus, there are $p = k + 1$ states. The model is illustrated for $k = 2$ in Figure 2. The transition intensities $\alpha_{0h}(t)$ for $h = 1,\ldots, k$ are given by the *cause-specific hazard* functions.

$$\alpha_h(t) = \lim_{\Delta t \to 0} \text{Prob}(\text{Dead from cause } h \text{ by } t + \Delta t | T \geq t)/\Delta t$$

where T is the survival time. The initial distribution is degenerate in 0, the only transient state of the model, that is, $\alpha_{hj}(t) = 0$ for all $h \neq 0$ and all $j \neq h$. The transition probabilities are the *overall survival probability*

$$P_{00}(0,t) = S(t) = \text{Prob}(T > t)$$

$$= \exp\left(- \int_0^t \sum_{h=1}^{k} \alpha_h(u)\, \mathrm{d}u \right)$$

and the cumulative incidences

$$P_{0h}(0,t) = \int_0^t S(u-)\alpha_h(u)du, h = 1, \ldots, k$$

Like the simple two-state model ($k = 1$) the competing risks model is Markovian and covariates may be included via regression models for the cause-specific hazards.

The Illness–Death Model

This model is illustrated in Figure 3, which by now should be almost self-explanatory. Often the time t is the age of the individual, and usually individuals will be assumed to be in state 0 at $t = 0$. However, individuals will not always be observed from $t = 0$ as shall be further discussed in Section Statistical Model Specification below regarding observational patterns. The mortality $\alpha_{12}(t)$ of the diseased (the *lethality*) may sometimes depend on duration d since entry to state 1 in addition to the dependence on age t. (Notice that, despite the notation, $\alpha_{12}(t)$ then depends on the *random* time of the most recent transition into 1.) If $\alpha_{12}(t)$ does not depend on d the process is Markovian, otherwise it is a semi-Markov process, which is clearly purely endogenous.

Figure 3 The illness–death or disability model.

Figure 4 Unidirectional illness–death model.

In Figure 3 we have indicated the possibility of reversibility: the transition back from state 1 to 0 is possible. It will turn out that the simple unidirectional model in Figure 4 is rather easier to analyze statistically. Thus, the transition probabilities in this model have simple explicit expressions.

$$P_{00}(s,t) = \exp\left(- \int_s^t (\alpha_{02}(u) + \alpha_{01}(u))\mathrm{d}u \right)$$

and (in the Markovian case)

$$P_{01}(s,t) = \int_s^t P_{00}(s,u-)\alpha_{01}(u)P_{11}(u,t)\mathrm{d}u$$

where

$$P_{11}(s,t) = \exp\left(- \int_s^t \alpha_{12}(u)\mathrm{d}u \right)$$

For this reason, and because of the desire to have a more detailed description, the reversible illness–death model is sometimes replaced by a model with one state for each new 'disease occurrence.' An example from nuptiality is indicated in Figure 5, where the possible transition from each state to death is omitted from the figure. (Only finitely many states are assumed!)

Interaction between Life–history Events

This Markov model, illustrated in Figure 6 describes the joint behavior of two life events A and B; if $\alpha_{0B} = \alpha_{A,AB}$ but $\alpha_{0A} \neq \alpha_{B,AB}$, A is called *locally dependent* on B but B is not locally dependent on A. The temporal order of events allows for this *asymmetric* concept of dependence which yields more

Figure 5 A model for marriage and dissolution.

Figure 6 Interaction between life history events.

information for drawing causal inference than the standard symmetric association concepts from cross-sectional studies. Similar duration dependence as in the illness–death process might be added. A model of this type was discussed by Aalen et al. (1980) for a study of interaction between menopause and a certain chronic skin disease (see also Blossfeld and Rohwer, 1995; Courgeau and Leliévre, 1992).

Bone Marrow Transplantation

A model combining most of the above features has been studied in detail (e.g., Klein et al., 1993; Keiding et al., 2001) as describing some of the possible states of a leukemia patient following bone marrow transplantation, see **Figure 7**. Patients have been given various kinds of therapy to temporarily keep the disease down, they are said to be in *remission*. In our context these patients are followed since bone marrow transplantation ($t = 0$), initially considered in state 0. Two different types of complications are considered: acute graft-vs-host disease (A), chronic graft-vs-host disease (C), and a special state AC is defined for those patients acquiring both A and C. Patients are followed until relapse of the leukemia (R) or death (D) while still in remission. Relapsed patients are not followed further in this context though, of course, a mortality rate among relapsed could be of interest in some settings. If all transition rates depend only on time t since transplantation, we have again a Markov process, but various kinds of duration dependence (semi-Markov process models) may also be relevant.

Counting Process Representation, Likelihood

Assume that multistate processes $X_i(t)$ such as described in Section Multistate Models are observed over intervals $[0, \tau_i]$ for individuals $i = 1,\ldots, n$. In this section, we will assume that τ_i is a fixed (i.e., nonrandom) time of termination of observation for individual i. Random right-censoring (Section Survival Data) is treated in Section Observational Patterns. Since $X_i(t)$ is constant between transitions, it is equivalent to record $X_i(0)$ and the *counting processes*.

Figure 7 A model for events following bone marrow transplantation: acute and chronic graft-vs-host disease, relapse, and death.

$$N^i_{hj}(t) = \#\,(\text{direct transitions } h \to j \text{ in } [0,t] \text{ for } i$$

described by the times T^{ik}_{hj} of these transitions, where

$$0 < T^{i1}_{hj} < \ldots < T^{iN^i_{hj}(\tau_i)}_{hj} \le \tau_i$$

Let

$$N_{hj}(t) = \sum_{i=1}^{n} N^i_{hj}(t)$$

It will turn out to be useful to also introduce $Y^i_h(t) = I\{X_i(t-) = h\}$ and

$$Y_h(t) = \#\,(\text{individuals at risk in state } h \text{ at time } t-)$$
$$= \sum_{i=1}^{n} Y^i_h(t)$$

Note that, for $t > \tau_i$, $N^i_{hj}(t) = N^i_{hj}(\tau_i)$ and $Y^i_h(t) = 0$; these can thus be considered to be defined on $(0, \infty)$.

For individual i denote the initial distribution $(\pi^i_h(0))$, the density of time-fixed covariates $f(Z_i)$, and the transition intensities $\alpha^i_{hj}(t)$, then the likelihood is

$$\prod_{i=1}^{n} f(Z_i)\pi_{X_i(0)} \prod_{h \ne j} \prod_{k=1}^{N^i_{hj}(\tau_i)} \alpha^i_{hj}\left(T^{ik}_{hj}\right) \exp\left(-\int_0^{\tau_i} \alpha^i_{hj}(t) Y^i_h(t)\,\mathrm{d}t\right)$$

It is very common to condition on Z_i and on the initial values $X_i(0)$ (the distribution of which may often be degenerate anyway), and consequently omit the factors $f(Z_i)\pi_{X_i(0)}$ from the likelihood. We shall do so without further comment in the sequel.

Recall from above that the notation $\alpha^i_{hj}(t)$ represents possible dependence of the transition intensity on the whole history $\mathcal{X}^i_t$ of the process. Thus, $\alpha^i_{hj}(t)$ may well contain covariates and other random elements, as already exemplified.

Statistical Model Specification

As discussed above the basic parameters in event history analysis are the *transition intensities* from which a full probabilistic description of the processes is possible. Thus, assessing their dependence on covariates, possibly using various stratifications, will often be an important first step of the analysis. However, frequently there are other targets of inference and additional functionals are useful, particularly various types of transition probabilities obtained by integrating certain functions of the transition intensities. Sometimes, it is therefore desirable to attempt to model such *marginal* features of the event history data directly. A final activity may be *prediction*, both as an illustration of the dynamics and for concrete practical purposes.

Markov Processes

The most important class of models is the (continuous time) *Markov process* $X(t)$ on a finite state space $\mathcal{S} = \{1,\ldots, p\}$

where the dependence of $\alpha^i_{hj}(t)$ on the history $\mathcal{X}_t$ introduced at the beginning of Section Multistate Models is only via the current state h of $X(t)$ (and possibly via time-fixed covariates). Statistical models are usually obtained by specifying the class of transition intensities $(\alpha^i_{hj}(t))$ for each individual i.

Constant and Piecewise Constant Transition Intensities

The simplest class of models is obtained by keeping the transition rates constant: $\alpha^i_{hj}(t) = \alpha^i_{hj}$. Piecewise constant intensities

$$\alpha^i_{hj}(t) = \alpha^{i(k)}_{hj}, t_{k-1} < t \leq t_k, t_0 = 0$$

form the next step up, and both of these choices are of widespread use, particularly in large studies in econometrics, epidemiology, sociology, and demography.

For ease of notation focus on the case with constant intensities and assume first that all individuals have the same transition intensities, $\alpha^i_{hj} = \alpha_{hj}$. The likelihood then simplifies to

$$\prod_{h \neq j} \alpha^{N_{hj}(\tau)} e^{-\alpha_{hj} S_h}$$

where $\tau = \max_i \tau_i$ and

$$S_h = \sum_i \int_0^{\tau_i} Y^j_h(t) \mathrm{d}t$$

Since this likelihood looks like one resulting from observing $N_{hj}(\tau)$ events in a Poisson process with intensity α_{hj} observed over the interval $(0, S_h)$, except that here S_h is random, this likelihood, and even the model, is often associated with Poisson's name. Maximum likelihood estimation is elementary, yielding

$$\widehat{\alpha}_{hj} = N_{hj}(\tau)/S_h$$

the classical *occurrence/exposure rate*. Asymptotic inference may be obtained from the information

$$-D^2 \log L = N_{hj}(\tau)/\alpha^2_{hj}$$

$$\mathrm{Var}(\widehat{\alpha}_{hj}) \sim \alpha^2_{hj}/N_{hj} \sim N_{hj}(\tau)/S^2_h$$

However, these variance expressions build on a correctly specified model and for that reason it is often desirable to apply *robust variances* based on the so-called *sandwich formula*, see, e.g., Keiding (2014).

Inclusion of time-fixed covariates is conveniently achieved log-linearly.

$$\alpha^i_{hj} = \alpha_{0hj} e^{\beta'_{hj} Z_i}$$

The Poisson likelihood easily accommodates this in what is often termed Poisson regression models, which may be treated using standard generalized linear model software.

Transition probabilities for the constant and piecewise constant Markov process models are explicit functions of the transition intensities (e.g., Chiang, 1968), allowing direct plug-in maximum likelihood estimation, as well as calculation of standard error estimates via the delta-method.

Other Parametric Models for the Transition Intensities

Although the piecewise constant model is often sufficient to describe the dependence of intensities on time, other possibilities exist. Certain mathematical functions of time may generate the model, such as the Gompertz-Makeham model for mortality.

$$\alpha(t) = \alpha + \beta\gamma^t$$

but except for mortality studies in actuarial and some demographic contexts such parametric models are used rather little. One reason for this may be the powerful development of methodology for nonparametric statistical inference, where $\alpha_{hj}(t)$ is left unspecified.

Freely Varying (Nonparametric) Transition Intensities

Assume first that the transition intensities are the same for all individuals but that they are allowed to vary freely with time: $\alpha^i_{hj}(t) = \alpha_{hj}(t)$. Statistical inference is then conveniently phrased in terms of the counting process approach pioneered by Aalen (1978) (see Andersen et al., 1993, for a detailed exposition). Estimators (which may be given a nonparametric maximum likelihood interpretation) of the integrated intensities

$$A_{hj}(t) = \int_0^t \alpha_{hj}(u) \mathrm{d}u$$

are obtained as the *Nelson–Aalen estimators*

$$\widehat{A}_{hj}(t) = \int_0^t \frac{J_h(u)}{Y_h(u)} \mathrm{d}N_{hj}(u) = \sum_i \sum_{k:0<T^{ik}_{hj} \leq t} \frac{1}{Y_h\left(T^{ik}_{hj}\right)}$$

$J_h(u) = I\{Y_h(u) > 0\}$, with variance estimators

$$\widehat{\sigma}^2\left(\widehat{A}_{hj}(t)\right) = \int_0^t \frac{J_h(u)}{Y_h(u)^2} \mathrm{d}N_{hj}(u) = \sum_i \sum_{k:0<T^{ik}_{hj} \leq t} \frac{1}{Y_h\left(T^{ik}_{hj}\right)^2}$$

An elaborate mathematical theory based on stochastic integrals and martingales is available to study exact and asymptotic properties of these estimators.

When estimates are desired of the transition intensities $\alpha_{hj}(t)$ themselves rather than their integrals, smoothing techniques are necessary.

An important feature of the nonparametric approach is its elegant generalization (due to Aalen and Johansen, 1978), to estimating *transition probabilities*. The basic tool is the (matrix) product-integral. Let I be the identity matrix and G a matrix-valued function. The corresponding *product-integral* is defined as

$$\prod_0^t (I + G(\mathrm{d}s)) = \lim_{\max|t_v - t_{v-1}| \to 0} \prod (I + G(t_v) - G(t_{v-1}))$$

where $0 = t_0 < t_1 < \ldots < t_n = t$ is a partition of $[0, t]$. In particular, if G is continuous and scalar

$$\prod_0^t (1 + G(\mathrm{d}s)) = e^{-G(t) - G(0)}$$

and if G is a scalar step function

$$\prod_0^t (1 + G(\mathrm{d}s)) = \prod_{k=1}^K \left(1 + \Delta G\left(t_{(K)}\right)\right)$$

where $t_{(0)} = 0$ and $0 < t_{(1)} < \ldots < t_{(K)} < t$ are the jump times of G and

$$\Delta G\left(t_{(k)}\right) = G\left(t_{(k)}\right) - G\left(t_{(k-1)}\right)$$

So far, transition intensities $\alpha_{hj}(\bullet)$ were only defined for $j \neq h$. Define now

$$\alpha_{hh}(t) = -\sum_{j \neq h} \alpha_{hj}(t)$$

and the intensity matrix function

$$A(t) = \left(\left(\int_0^t \alpha_{hj}(u)\mathrm{d}u\right)\right)$$

Then the matrix $P(s, t) = ((P_{hj}(s, t)))$ of transition probabilities

$$P_{hj}(s, t) = \mathrm{Prob}(X_i(t) = j | X_i(s) = h)$$

is given by

$$P(s, t) = \prod_s^t (I + A(\mathrm{d}u))$$

The *Aalen–Johansen estimator* of $P(s, t)$ is obtained by plugging the matrix of Nelson–Aalen estimators $(\widehat{A}_{hj}(t))$ into this formula.

$$\widehat{P}(s, t) = \prod_s^t (I + \widehat{A}(\mathrm{d}u))$$

For the simple two-state model for survival data, $\widehat{P}_{00}(0, t)$ reduces to the classical Kaplan and Meier (1958) estimator $\widehat{S}(t) = \prod_{T_i \leq t}(1 - \mathrm{d}N_{01}(T_i)/Y_0(T_i))$ of the survival function $S(t)$.

As documented in detail by Andersen et al. (1993: Section IV.4), there is a well-developed theory, again based on stochastic integrals and martingales, about the asymptotic properties of the Aalen–Johansen estimator.

Semi- and Nonparametric Regression Markov Models

For Markov models with several states, there will often be too little empirical basis for estimating freely varying transition intensities between all states, so that more parsimonious models are required. One possibility (demonstrated in detail by Klein et al., 1993; Keiding et al., 2001; for the bone marrow transplant example above) is to postulate that transition intensities *into* a state are proportional: $\alpha_{hj}(t) = \alpha_{0j}(t)e^{\beta_h}$ for all (relevant) h. The statistical analysis of this model is equivalent to a Cox regression model with time-dependent covariates indicating the departure state h.

The semiparametric Cox model (proposed by Cox (1972a,b) for survival data and for renewal processes, respectively) may also be used for including covariates not depending on time, this preserving the Markov property. The consequent generalization of the Aalen–Johansen estimator was studied by Andersen et al. (1991b, 1993: p. 512ff.) and implemented for the bone marrow transplant problems just mentioned. An alternative, nonparametric *additive* hazard regression model is due to Aalen (1980) with general discussion by Martinussen and Scheike (2006) and Aalen et al. (2008).

Beyond Markov Processes

The most important deviations from the Markov property in practice are various kinds of duration dependence, where transition intensities depend on other time origins than $t = 0$, typically the time at entry to the present state. There are two main approaches to handling these.

As long as transition intensities depend only on one time origin each (e.g., all intensities depend only on duration in the present state), a model for the multistate process may be obtained by combining independent submodels for each transition intensity. These may, in turn, be modeled as constant or piecewise constant or by non- or semiparametric models, and as long as there is a unidirectional flow in the model, transition probabilities are still straightforward explicit functionals which may be estimated by plugging in the intensity estimates. Variance calculations may, however, become less direct.

More elaborate models will include several time origins (such as both age, disease duration, duration since marriage dissolution), often in piecewise constant intensity models or semiparametric regression models such as the Cox model. An example concerning mortality of diabetics with or without nephropathy was studied by Andersen (1988), see also the consequences for Danish life insurance premiums (Ramlau-Hansen et al., 1987).

Nonparametric estimation of transition probabilities in the non-Markov unidirectional illness–death model (**Figure 4**) was studied by Meira-Machado et al. (2006) while, more generally, Datta and Satten (2001) showed that *state occupation probabilities* $\pi_h(t)$ may be estimated using the Aalen–Johansen estimator without a Markov assumption. Also, without a Markov assumption, transition probabilities may be estimated from a specification of all transition intensities using *micro-simulation* (e.g., Mitton et al., 2000).

The heterogeneity between individuals cannot always be accounted for by *observed* covariates, and at least some residual heterogeneity will have to be modeled as random variation. An important class of models here is the multiplicative *frailty models*, obtained by postulating random (usually transition-specific) *frailties* W^i_{hj}, and conditional transition intensities.

$$\alpha^i_{hj}\left(t | W^i_{hj}\right) = \alpha_{0hj}(t) W^i_{hj} e^{\beta' Z_i}$$

(e.g., Hougaard, 2000). By integrating over the (multivariate) frailty distribution, observable features of the multistate model may be derived.

Hypothetical Calculations in Multistate Models

As mentioned earlier, there is often considerable interest in studying the consequences of the estimated transition intensities by calculating summary measures such as transition probabilities. When a full model has been estimated, this can be done not only of the model observed in this world but, also, the consequences of an assumed (or fitted) multistate model may be further illustrated by calculating transition probabilities

in hypothetical models obtained by changing some of the parameters. An elaborate example of this was given by Keiding et al. (2001) for the bone marrow transplantation context, but similar calculations have been performed in the competing risks model ever since the first discussion by Bernoulli (1760) of the effect on population mortality of removing smallpox through vaccination. The interpretational justification of such calculations was discussed heatedly, particularly in the 1970s (see Gail, 1975; Prentice et al., 1978; Kalbfleisch and Prentice, 2002; Chapter 8), see Andersen and Keiding (2012) for a recent contribution to that discussion.

Partial Model Specification

We have so far assumed that the multistate model was completely specified through statistical modeling of all transition intensities. In a series of papers (Pepe, 1991; Pepe et al., 1991; Pepe and Mori, 1993; Couper and Pepe, 1997), Pepe and coworkers have developed estimates of certain functionals in multistate models without assuming a full probability structure. One example is the *prevalence* of a transient condition indicated by state c defined as

$$P_{0c}(0,t)/\sum_{j\in\mathcal{S}_T} P_{0j}(0,t)$$

where $\mathcal{S}_T$ is the set of transient states and 0 is a fixed initial state. The idea is to estimate numerator and denominator separately by simple linear combinations of Kaplan–Meier estimates. Easily applicable variance estimates are then available and in one application (Klein et al., 2000) it was shown that the precision of the Pepe approach was close to the more elaborate (and restrictive) complete Markov model.

Regression models for certain marginal features of a multistate process have been studied both in specific cases and in a more general framework. Thus, the model by Fine and Gray (1999) provides a direct link between a cumulative incidence function in a *competing risks* model and (time-fixed) covariates, and Lawless and Nadeau (1995) (see also Lin et al., 2000) studied a similar model for the mean number of events in a *recurrent events* model. General approaches to regression models for state occupation probabilities in a multistate model (however, with much emphasis on the simple competing risks model) were provided by the 'direct binomial regression models' by Scheike and Zhang (2007) and Scheike et al. (2008) and by the use of 'pseudoobservations' (e.g., Andersen et al., 2003; Klein and Andersen, 2005). Since these approaches are not likelihood based, estimated variances for regression coefficients are obtained using the *sandwich formula* for the relevant *estimating equations*.

Another example of partial model specification occurs when the model contains time-dependent covariates which are not purely endogenous. In fact, for time-fixed covariates we just (cf Section Counting Process Representation, Likelihood) conditioned on their observed values without specifying their distribution, $f(Z_i)$, but for time-dependent covariates such a conditioning is more tricky. Formally, the likelihood will contain factors for the stochastic development of $Z_i(t)$ given the history $\mathcal{F}_{t-} = \mathcal{X}_{t-} \vee \mathcal{Z}_{t-}$ and the likelihood described in Section Counting Process Representation, Likelihood, is not the full likelihood but only a partial likelihood for the parameters for the transition intensities $\alpha^i_{hj}(t)$. This means that inference for the transition *intensities* may be based on this partial likelihood whereas the transition *probabilities* typically will depend also on the parameters in the model for $Z_i(t)$. Thus, if the model contains time-dependent covariates which are not purely endogenous then transition probabilities cannot be estimated using only a partial model specification. One approach is to set up a *joint model* for the multistate process $X_i(t)$ and the time-dependent covariates $Z_i(t)$. When $Z_i(t)$ only takes a finite number of values this joint model could, again, be a multistate model where $Z_i(t)$ is now endogenous (e.g., Andersen, 1986; Andersen et al., 1991b; Cortese and Andersen, 2010). Examples of more general joint models were presented by Wulfsohn and Tsiatis (1997) and Henderson et al. (2000), see also the review by Tsiatis and Davidian (2004).

A simpler approach for this problem which may be particularly useful when *dynamic prediction* is an issue is to use *landmarking* (e.g., van Houwelingen, 2007; see also van Houwelingen and Putter, 2012). Here, a series of (e.g., Cox regression) models is set up, each at a prechosen landmark time, and each model then conditions on the current values of possibly time-dependent covariates.

Time-Dependent Confounding: Beyond the Range of Event History Analysis

A main purpose of including covariates in event history models is to correct effect estimates for confounding, and the necessary care to take in this connection is well known as long as only confounders known at baseline are considered, the *time-fixed* covariates. When considering 'controlling for' *time-varying* or *time-dependent* covariates, new interpretational difficulties arise, and these are not directly addressed by the technical statistical considerations around likelihood construction mentioned in Section Partial Model Specification. Pioneered by Robins (1986) in connection with the century-old attempts to obtain a conceptual framework for the healthy worker effects, the core problem may be illustrated by **Figure 8**. Here X_t and Y_t are covariate and response at time t. Since Y_t is a confounder for the association between X_t and $Y_{t+}1$, we should control for (i.e., condition on) Y_t, but because Y_t is also intermediate between X_{t-1} and Y_{t+1}, we should not dilute the effect between X_{t-1} and Y_{t+1} by conditioning on Y_t. Using the counterfactual framework for causal analysis, Robins (1986) defined causal effects in this context and explained (see in particular Robins et al., 1992) that Cox models with time-dependent covariates cannot estimate this causal effect. Robins's work has generated a large literature about methods for handling time-dependent confounding, see the excellent tutorial by Daniel et al. (2013) for a survey. These methods

Figure 8 Illustration of time-dependent confounding.

go beyond the event history analysis framework discussed in this article.

Observational Patterns

As emphasized in the introduction, event history models are rarely observed completely. Some patterns of incomplete observation are more easily handled than others, and this section aims at introducing some of the more important classes.

Delayed Entry and Right-Censoring

Many of the statistical methods introduced in this article depend directly or indirectly on the likelihood representation of Section Counting Process Representation, Likelihood. Two patterns of incomplete observations are particularly easily tractable, because they lead to only minor modification of the likelihood: *Delayed entry* (or *left-truncation)* where individual i enters at some time V_i and *right-censoring* where nothing is known about i after some time U_i. Both V_i and U_i may be random although only dependent on the previous history of the process (see, e.g., Andersen et al., 1993, for precise specification of this and further discussion). The reason for the particular tractability of these mechanisms is that the at risk indicator $Y_h^i(t) = I\{X_i(t-) = h\}$ just needs to be amended to

$$Y_h^i(t) = I\{X_i(t-) = h, V_i < t \leq U_i\}$$

and the likelihood-based statistical methods then all go through.

The situation is more complex when modeling marginal features directly. Thus, in such cases simple inference will typically rely on an assumption that right-censoring is completely independent of the multistate process and otherwise the way in which right-censoring depends on covariates needs to be modeled explicitly (e.g., Fine and Gray, 1999; Scheike and Zhang, 2007). Also, left-truncation becomes much more tricky for marginal models (Geskus, 2011).

Interval Censoring

An important class of incomplete observational patterns consists in the times of some (but often not all) transitions not being known exactly but only up to an interval, e.g., between visits to a clinic or between censuses. (The *number* of transitions is usually assumed to be known.) A classical approach in demography (Hoem, 1969) is to approximate the exposure.

$$S_h^i = \int_{V_i}^{U_i \wedge \tau_i} Y_h^j(t)\mathrm{d}t$$

another to impute values in the observation interval for the time at risk. Systematic studies of nonparametric maximum likelihood estimation under interval censoring in the unidirectional illness-death model are by Frydman (1992, 1995), Frydman et al. (2013), Joly and Commenges, 1999 and Joly et al. (2012). Kay (1986) and Andersen et al. (1991a) exemplified interval-censored observation in the reversible illness-death model, using piecewise constant intensity models. Sun (2006) summarized methods for analysis of interval censored survival data.

Conditioning in Multistate Models

Many observational patterns in event history analysis may be described by conditional distributions in simpler models, which often describe 'direct' observations that are practically unobtainable. A prime example is the left-truncation just described, another is right-truncation with widespread use in studies of AIDS patients whose development is often observed conditional on having contracted the disease before the study entry. For general discussions see Kalbfleisch and Lawless (1989), Keiding and Gill (1990), and Gross and Huber-Carol (1992). A more elaborate application of such retrospective observational plans obtained by conditioning in an underlying prospective Markov process model was documented by Aalen (1980) for the four-state interaction of life history events example described above (**Figure 6**).

An important sampling frame for the illness–death model without recovery is the *prevalent cohort study* where a cross-sectional sample of diseased is taken at a fixed calendar time. Keiding (1992) (see also Lund, 2000) discussed the conditions for correct inference on the mortality $\alpha_{12}(t)$ based on follow-up of the diseased, studied under left-truncation, and compared with inference based on the *length-biased* durations which include the retrospective time from disease onset, as well as to the *forward recurrence time* from sampling to death, assuming stationarity.

A comprehensive substantive discussion of biases in prevalent cohorts was given by Brookmeyer (1998). Retrospective estimation of incidence based on the disease onset information of the survivors and independent lethality information was exemplified by Keiding et al. (1989), see also Ogata et al. (2000).

Sometimes interval censoring is extreme: in a cross-sectional study it is for all individuals only known whether or not an event has happened at age of sampling. Methodology for analyzing such *current status* data was surveyed by Sun (2006), cf Keiding (1991, 2006). *Current duration* data (backward recurrence times) may sometimes be used to estimate mortality from the age distribution of those living at a cross-section, assuming stationarity. Keiding et al. (2002, 2012) and Scheike and Keiding (2006) surveyed application of this approach to time-to-pregnancy studies, and Slama et al. (2006, 2012) applied the technique to a French telephone survey of time to pregnancy.

Concluding Remarks

We have attempted to provide an exposition of problems and solutions in event history analysis in continuous time. The probability models are continuous-time nonhomogeneous Markov processes and generalizations, the main statistical techniques are log-linear intensity models as well as non- and semiparametric counting process-based models. It is emphasized that considerable care (and consequent methodological innovation) is motivated by the many indirect observational patterns.

Abstract

This article introduces the development of the method of event sequence analysis (SA) in social science. It begins by locating it in the tradition of exploratory data analysis. It then lays out various existing sequence analytic strategies that vary in the amount of narrative detail they retain as well as some methodological issues with SA. It concludes with a discussion of the potential applications of SA and its promise for adoption within social science following from algorithmic developments in biology and computer science.

Event sequence analysis (SA) methods are methods seeking patterns that recur across a number of sequences. They are applied to data on social sequences (occupational careers or life courses, for example) (e.g., Kogan, 2007; Malo and Muñoz-Bullón, 2003) as well as to historical sequences (of policy adoption, for example) and cultural sequences (different versions of a particular story, for example). The most common techniques for sequence analysis are optimal matching techniques, so-called because they operate by finding distances between pairs of sequences on the basis of an 'optimal match' of the two sequences – a minimal series of operations that transform one sequence into the other. In computer science, the optimal matching problem is usually called the string alignment problem. In social sequence analysis, the matrix of pairwise distances between sequences is used in any standard two-way analysis scheme like scaling or cluster analysis to produce categorizations or dimensionalizations of a sequence space. Sequence analysis has been used in a variety of empirical areas with varying success. It is a descriptive rather than causal technique and will typically be used in combination with causal methods rather than to their exclusion.

SA methods are methods seeking patterns that recur across a number of sequences. They are applied to data on social sequences like occupational careers or life courses, as well as to historical sequences such as might emerge in policy adoption or in the development of organizational structures and to cultural sequences like the various orders of elements in different versions of a widespread ritual or story. The most common techniques for seeking these patterns are standard sequence comparison algorithms widely available in biological software.

Sequence Analysis and Its Origins

Sequence analytic methods are part of a general turn toward the use of exploratory techniques in social science. As such they stand with techniques like cluster analysis, multidimensional scaling, and factor analysis. All of these methods seek radical simplification of the data space in the hope that analyzable patterns can be found. They contrast with the many causal techniques that take high dimensionality of the data space for granted and analyze that space by seeking to find the impact of a set of 'independent' dimensions on one 'dependent' dimension of the data.

This turn to exploratory techniques has a number of sources. One of these has been the stockpiling of immense data sets analyzable in many diverse ways. Another has been the more or less exploratory use of causal methods enabled by commodification; where hundreds of regressions precede those actually reported, the idea of classical hypothesis testing becomes questionable. Exploratory analytic techniques have generally been more common in applied social science rather than in academic work, having their widest use in market research. Within the academy, they have seen wider use in psychology than in any other social or behavioral science. While not unknown in political science and sociology (see, e.g., the various works of E.O. Laumann, such as Laumann and Knoke, 1987), they are virtually absent from economics.

The turn to sequence analysis in particular, however, proceeded from a critique of causal conceptions articulated by Abbott (1983, 1988, 1997) and Abell (1987). Both writers criticized what they called the 'variables' tradition for assuming that the social world is best imagined in terms of independent units of analysis whose properties 'cause' one another rather than in terms of chains of actions and events. Abell's argument was the more abstract, being rooted in a theory of social action based on rational choice. Abbott's was more empirical, being driven by the problem of comparing histories across social units. Both writers sought methods that would identify and compare similar chains of events across varieties of social sequence data.

Sequence analytic strategies vary in the amount of narrative detail they retain. Essentially, the more narrative detail retained the less powerful the modes of generalization or pattern search available. Strongest in retaining detail is David Heise's (1989) event structure analysis (ESA), which is essentially an interactive program for establishing the essential narrative dependencies in a complex story. The analyst inputs events and answers questions posed by the program about which events depend on which others and how. The program then produces a minimal representation of these dependencies. While it is very useful for establishing rigorous narrative patterns, ESA has not seen widespread use as a technique for generalizing about sequence patterns (for an example, see Griffin, 1993).

Abell's (1993) method for narrative analysis retains less empirical detail. It begins with a 'narrative table.' The table is essentially a matrix of actors across actions, implicitly like the Heise pattern, but ignoring the specific content of events to focus on the network 'shape' of the connections between events. Narratives are similar if they can be reduced homomorphically to the same network structure. Abell's method has not seen substantial use, perhaps because his notion of similar narrative structure is not seen by empirical analysts as of immediate utility, despite its theoretical elegance. (But see the comments by various writers on Abell's techniques in *Journal of Mathematical Sociology* 18, Numbers 2 and 3.)

Abbott's approach simplifies sequence data far more than do those of Abell or Heise, insisting on unilinear sequences of simple events. These sequences are then compared using the widely available pattern-matching algorithms that have emerged in computer science and biology since the 1970s (for a review, see Abbott and Tsay, 2000; Durbin, 1998; Von Heijne, 2012; Brzinsky-Fay and Kohler, 2010). As might be expected given its simplicity, Abbott's method has seen the widest use of SA methods. It is variously referred to as sequence analysis, optimal matching analysis, or optimal alignment, the latter two being names for the standard algorithms used to measure resemblance between sequences.

Abbott's method (hereafter abbreviated OM for its most common name, optimal matching) presupposes a set of 'sequence data,' that is, a set of strings (sequences), each one of which is a vector of elements representing a succession of events in some discrete order. In career data, these might be sequences of jobs held in each month over some period. In cultural analysis, they might be orders of gestures in rituals. Events can recur or return an indefinite number of times, and there is no necessary constraint of equal length on the sequences.

Simply described, Abbott's method consists in using dynamic programming algorithms to define distances between all possible pairs of sequences in a data set. These distances are then analyzed by clustering or scaling to produce some typology of sequence types. This typology may be used as a simple description or as a dependent or independent variable in more standard causal techniques. Thus stated, Abbott's formulation of sequence analysis for the social sciences is equivalent to what is known in computer science as the multiple string alignment problem, on which there is an extensive literature (see Gusfield, 1997: Chapter 14).

Algorithms for multiple string alignment are typically based on simple algebra establishing 'Levenshtein distance' between two strings, the minimum number of edit operations (insertions, deletions, replacements) necessary to transform one string into the other. Although in some applications more complex operations have been investigated (see papers in Sankoff and Kruskal, 1983), the string comparison literature has focused on the simplest three operations.

Finding the minimal edit distance between two sequences is a matter of inspection unless varying weights are placed on varying operations. Typical weighting schemes involve a fixed insertion and deletion weight coupled with replacement weights that vary in terms of what replaces what. Under such weighting schemes, the minimal edit distance problem must be solved by a simple dynamic recursion usually attributed to the classic paper of Needleman and Wunsch (1970).

Sequence analysts may also be interested in the question of whether a set of sequence data has some common subpattern, i.e., whether there is a characteristic subsequence that may appear in many or most sequences. This problem, known technically as the multiple local alignment problem, has been solved by a Gibbs sampling algorithm due to Lawrence et al. (1993). Abbott has applied it to the analysis of rhetorical subsequences in sociological articles (Abbott and Barman, 1997).

Methodological Issues

Two kinds of methodological issues have arisen in the area of SA methods. In the main, these concern OM methods, as these are the most widely applied. The first such issues are those proper to the method itself, the second those concerning its utility. Like all methods, OM has its own internal assumptions and difficulties. Issues of data coding have vexed many users, although there is some indication that the methods, like most exploratory methods, are less vulnerable to the vagaries of coding than methods taking the data as given. One coding issue in particular has seemed worrisome, that of coding the underlying temporality. Some have used regular time intervals; others have collapsed continuous episodes. Another important issue has been the setting of weights of replacement and insertion/deletion. A wide variety of schemes have been used, but relatively few analysts have studied the impact of varying schemes. It is clear that all these areas need more experimentation than has presently been done. This is also true in terms of validation. Most typologies and clusterings in the OM literature have been accepted as is, without further validation. A few papers have used Monte Carlo validation methods.

The other major issues with OM methods in particular, as with SA methods more generally, concern their utility. There are two versions of this concern, one small scale, the other more general. The small-scale issue involves what SA methods can really add to event history or other methods investigating hazard rates for particular kinds of events. These are the standard 'causal' methodologies that are applied to sequence data. In areas where such methods are well developed (examination of careers, labor force involvement, and marital status), SA methods seem to standard analysts to have little to add. In other areas, however, particularly in the analysis of sequential cultural structures like stories or rituals, event history methods themselves have no utility. It is not yet clear whether SA methods can provide standard-method career analysts with results that will surprise them. (Like any paradigm, event history methods to some extent enforce criteria for results that favor their own types of results.) All the same, the eventual success of SA methods will depend on finding regularities that event history methods cannot find. A clear discussion (and example) of such regularities appears in Stovel et al. (1996).

The more general question about SA's utility seems to have a clearer answer. There is little question that the broad project of employing pattern-matching techniques in social science data is a sound one. Partisans of SA methods entered the area largely to carry out a theoretical agenda that began as an attack on standard methodologies. But in turning to the computer

science and biological literature, they found one of the most rapidly advancing areas of modern scientific methodology. Seeking patterns directly, rather than through hypothesized models, is not only good science, but also may be one of the only means of addressing the monumental data sets of the future.

Future Developments

To date, most applications of SA have involved a fairly limited substantive range. The most common application has been to career data. Some have worked with particular job histories, others with broader occupational classes. Still others have combined family data into these patterns. A number have worked with the 'careers' of larger social organizations – professions, counties, and nations. Still other applications have involved patterns of activity – at travel agencies, libraries, decision-making groups, and the like. A final group of studies has considered cultural artifacts – stories, dances, academic articles, and so on. As these examples show, the method has been typically applied where standardized patterns are strongly expected.

Most early SA was done using fairly simple computer packages adapted for the purpose. At the beginning of the twenty-first century standard biological packages are being adapted for social use (e.g., CLUSTAL by scholars at the University of Strasbourg). Applications of SA can be expected to grow more common once the actual algorithm (not just the weighting scheme) can be tailored to the type of sequence regularity expected in the data (e.g., Gauthier et al., 2010).

The extraordinary flowering of pattern-matching methods in biology and computer science will undoubtedly lead to greater application of these methods within social analysis. They are already widely used in market research, of course, and therefore constitute a central part of what is by far the most extensive and comprehensive form of social scientific analysis at present. To be sure, the causal paradigm against which SA methods were developed remains strong within the empirical social sciences. But in the past, widespread availability of new methods has led to wholesale adoption even in the face of earlier paradigms. Indeed, the present causal methods spread precisely in this way. Given the rise of pattern-matching as a general strategy of scientific inquiry, SA and related methods will almost certainly spread. They will also constitute the entering wedge of a much broader set of descriptive approaches to social reality that can be expected to transform social inquiry in the next decades.

Abstract

The study of everyday life is an interdisciplinary field that stands for a special interest in the commonplace and the seemingly trivial routines and activities of daily life as well as a focus on ordinary people as creative actors rather than passive consumers or objects of domination. Like few other similar concepts, the study of everyday life has been used not only as a research perspective or analytical tool but also as a research ideology. The study of everyday life developed in the postwar period as an alternative to, or critique of, mainstream traditions in the social sciences, often with a focus on anthropological, ethnographic, and qualitative approaches.

The Study of Everyday Life

From the 1960s onward, the concept of 'the study of everyday life' became an increasingly popular notion in many social sciences, such as anthropology, history, and sociology, as well as in the expanding field of cultural studies.

It has come to signal a special interest in the commonplace and the seemingly trivial routines and activities of daily life as well as a focus on 'ordinary people' as creative actors rather than passive consumers or objects of domination. The different ways in which this seemingly simple concept has been put to work illustrate changing concerns in social and cultural research, as well as conflicts between different research paradigms. Like few other similar concepts, the study of everyday life has been used not only as a research perspective or analytical tool but also as a research ideology. The study of everyday life often developed as an alternative to, or critique of, mainstream traditions.

The use of the concept as an alternative approach means that it is constantly being constructed in opposition to something else. It can be organized as the study of the life and thoughts of ordinary or common people against that of elites, intellectuals, or experts. It can be defined as the routines, habits, and phenomena that tend to be neglected because their 'everydayness' makes them invisible or self-evident, unlike colorful rituals, celebrations, or other activities with high visibility or prestige. Here, it is 'the everyday' as contrasted to 'the Sunday best' in social life, working with polarities like mundane/sacred, informal/formal, repetitive/unique, and trivial/special. Everyday life can further be seen as the arena of expressions and meanings threatened by invasion from above, by institutions like the state, the market, or just 'the system.' This perspective favors a view of everyday life as resistance against domination. The focus on resistance is often linked to a view of everyday life as a site of cultural creativity. Finally, 'the study of everyday life' often defines a research orientation rather than an empirical field. It is then seen as a certain style of doing research, usually with a focus on qualitative and ethnographic methods – exploring the hidden worlds of daily life. The argument is often that by focusing on seemingly banal phenomena new and sometimes surprising analytical insights into major social or cultural issues may be produced.

The study of everyday life has emerged as an arena of intense cross-disciplinary dialogues, but it is also an interest that has developed in a constant interchange with new public and political ideas about the importance of everyday life (see Gullestad, 1991) (*see* Common Sense, Anthropology of).

The Making of a Concept

The development of everyday life as a research topic is thus a complex one. It has entered the social sciences along many paths and in this process been charged with very different theoretical and ideological meanings. There are two nineteenth-century traditions that can be seen as starting points for the twentieth-century interest in the study of everyday life. The first of these was the works of those cultural historians who in the late-nineteenth century turned to the everyday life of 'ordinary people' to create an alternative to the classic history of kings and elites. The second tradition was the interest among early social researchers and reformers in exploring the lives of urban poor or rural peasants, starting with Henry Mayhew's classic work *London Labor and the London Poor* of 1861.

Sociological Approaches

It was this latter interest in questions of social welfare that influenced the interwar ethnographic studies of the so-called Chicago School of American Sociology. An early example is Nels Anderson's book *The Hobo: The Sociology of Homeless Men* of 1923.

This interest in urban everyday life of the Chicago School was developed further by the new generations of postwar American sociologists. Behind the new label 'the sociology of everyday life' very different theoretical traditions and research perspectives were found. One was the symbolic interactionism of Erving Goffman's (1959) pioneering work *The Presentation of Self in Everyday Life*, with its qualitative, ethnographical approach to the seemingly trivial or invisible routines of the everyday as it surfaced in patterns of social interaction. For early phenomenological contributions to this sociology of everyday life, see, for example, Schutz (1973) and Douglas (1971). The third new approach was ethno-methodology (see Garfinkel, 1984), mainly devoted to understanding the construction of

common-sense knowledge in everyday life. Today, the sociology of everyday life usually stands for a qualitative and ethnographic approach (see Glassner and Hertz, 1999).

In France, the sociology of the everyday developed along very different lines. Here, the studies of popular mentalities in the Annales School of social history and especially the works of Fernand Braudel created an early analytical interest in the role of everyday life for understanding society. The sociologist and rather unorthodox Marxist Henri Lefebvre started to explore the concept of the everyday already in the interwar period and published a number of books on the topic between 1947 and 1991 (e.g., Lefebvre, 1971). His interest in everyday life was connected with the rapid modernization France underwent especially after the Second World War with the creation of a new consumer-based and standardized everyday life. He used the term 'everydayness' (*le quotidien*) to describe what he saw as the banality and conformity of modern everyday life and the ways in which it was colonized by modern capitalism. But Lefebvre's approach was not only centered around questions of alienation and domination. His treatment of the problems of 'everydayness' also stressed the ways in which social scientists underestimated the role of the everyday, not only as a site of domination but also as an arena with potentials for transcendence and change – the peak experiences or special moments embedded in it (see Shields, 1999).

Lefebvre's discussions of everyday life had a strong philosophical profile, which may be one of the reasons his work did not come to inspire empirical studies in the same way as the work of another French sociologist, Michel de Certeau (1984), whose book was very influential in shaping the approaches to the study of everyday life in many disciplines during the 1980s and 1990s. Lefebvre and de Certeau both shared an interest in the uses of space in everyday life, but the similarities end there. Unlike Lefebvre, de Certeau focused on everyday life as an arena of cultural creativity and resistance, and above all on consumption as creative cultural production.

Anthropological Approaches

In anthropology, the actual concept 'study of everyday life' was not at first used very frequently, in spite of the fact that anthropology often was seen as the science of the everyday with its ethnographic and qualitative explorations of life in different settings over the world. One reason for the lack of an explicit use of the concept of everyday life was that it was seen as a cultural category belonging to the modern Western world. In non-Western societies, this polarity between the everyday and its counterparts, however defined, did not seem very relevant. In the broad anthropological approach to the study of culture, there was no need for a subcategory labeled everyday culture.

In many ways, the interdisciplinary interest in studies of everyday life among historians and sociologists from the 1960s and onward meant an anthropologization of both approaches and theoretical frameworks. It was not only the ethnographic methods and the metaphors of 'discovering' and 'exploring' everyday life as a hidden but also the exotic culture that accounted for this anthropologization. The anthropological connection also had to do with studies of everyday life emphasizing a cultural perspective on society. It was in the habits, rituals, routines, and traditions of daily life that 'culture' was embedded, as invisible to the actors as 'water to the fish,' to quote a popular metaphor from the 1970s.

A much more explicit use of the category of the everyday was found in the anthropological branch of European ethnology, which from the 1960s onward redefined itself as a discipline in which the study of everyday life in European settings, past and present, was central. This transformation may serve as an example of how the concept came to be given strong symbolic and ideological charges (see Frykman and Löfgren, 1996).

As European ethnologists in the 1960s oriented their research toward modern industrial society rather than vanishing peasant traditions, the basic concept of folk culture was exchanged for the study of the everyday and 'the ordinary people.' These new concepts not only signaled a break with earlier generations but also worked as a boundary marker against neighboring disciplines. Ethnologists studied everyday life with a qualitative perspective unlike sociologists and historians; the concept of everyday life was used to show that the ethnological interest in society was not concerned with formal institutions and macrostructures. In reality, the concept was thus not about the contrast between everyday and non-everyday phenomena, but a way of stressing a research interest focusing on neglected groups, activities, and spheres.

Everyday Life and Cultural Creativity

Another research tradition in which the notion of everyday life became very important was the emerging field of cultural studies. As in European ethnology, this interest in everyday life during the 1980s and 1990s was linked closely to the new concept of cultural creativity.

Like the notion of everyday life, the concept of creativity functioned as a counterargument in cultural research. Groups and settings that at first glance seemed characterized by passivity, simply reproducing dominant patterns, were in the new studies coming out as culture builders and bricoleurs: busy reworking, elaborating, and thickening their everyday lives with new meanings and routines. This approach is very striking in de Certeau's work as well as in many of the studies made by the so-called Birmingham School of cultural studies. A good example is Willis' (1990) book *Common Culture: Symbolic Work at Play in the Everyday Cultures of the Young*. Here everyday creativity becomes not only a counterargument against the presupposition that creativity is an elite resource, a cultural capital of the gifted, of artists, writers, intellectuals, and so forth, but also against the notion that modern mass consumption is a passifying, homogenizing force in people's lives.

When consumption was redefined as 'cultural production' or 'symbolic production,' the creativity of everyday life moved in to occupy a central position in this production process. This emphasis on cultural creativity as resistance must be seen as a reaction against an earlier discourse on the seduction of mindless consumers: locked up in the iron cage held together by market forces. Creativity became, in some ways, the weapon of the weak – a positive strategy of resistance. More rarely, the concept was used to describe strategies of dominance and oppression; other terms were used for the creative and imaginative ways of control and manipulation.

The pairing of cultural creativity and everyday life can thus be seen as an attempt to redress the balance, to develop a more actor-oriented approach in studies of mass consumption. In this process, however, the 'when, where, how, why, and who' of cultural creativity in everyday life was narrowed down and produced certain paved roads: a tendency to over-research some aspects and arenas and overlook others (see Löfgren, 1997).

This slanting of the two concepts was not a very conscious process. It started with the focus on consumption as creativity, a creativity much focused on symbolic production and expressive forms in what Featherstone (1991) has called the aesthetization of everyday life. This very selective emphasis was made more narrow by a marked concentration on specific social settings, above all youth cultures with their constant experimentation with identities and reworking of mass media and mass consumption styles, images, and commodities.

With a selective focus like this, cultural creativity became a very positive concept. It was seen as enriching, elaborating, and 'thickening' everyday life, a process through which people make their daily existence colorful, unique, specific, distinct, and above all positive. The perspective usually was reserved for those defined as the underdogs of the modern world: consumers, workers, women, teenagers, and colonial and postcolonial subjects, and this is where the concept is linked closely to ideas of counter-hegemony, to the tactics of resistance in the world of mass consumption or in postcolonial processes of globalization.

Problems and Potentials

Just like everyday life, creativity became a concept mainly for the age of late modernity. The academic interest in the two concepts mirrors a public and political concern too – especially in Northern European and North American settings – which had its roots in the countercultures of the 1960s and 1970s and the interests in alternative lifestyles as well as the democratization of cultural expression. During this period, the idea of the importance of everyday life became a powerful political symbol, condensing and unifying a number of sometimes conflicting values (see Gullestad, 1991). Everyday life was 'where the action was,' the location of 'real or authentic life.' By studying and engaging this arena, silent groups and interests could be given a voice.

Such political and popular interests influenced academic research. Some activities and people easily came to be seen as more everyday than others. Another danger of this perspective was that everyday life was too easily seen as something 'down there,' in a way that seldom reflected upon the problem of what the opposite of the everyday was supposed to be. It was forgotten that everyday life existed not only in retirement homes or on the streets but also in the corridors of power, that there were everyday practices not only in immigrant suburbs but also in scholarly research projects. Researchers who sometimes said that they wanted to 'get out into everyday reality' missed the point that what is interesting about the everyday is that it is ever-present.

Taking such ambiguities and possible ideological overtones into account, research interest in the study of the everyday has on the whole been important both in revitalizing and in redirecting scholarly attention to the role of the seemingly trivial activities and ideas embedded in the commonplace. During the last decades of the twentieth century, the study of everyday life constituted a very productive cross-disciplinary field, developing innovative research strategies for destabilizing or problematizing the taken-for-grantedness of much daily life.

The study of the everyday has also been a strategy to avoid paved roads in research and develop back-door entrances to major issues. Two examples may illustrate such strategies. The first is taken from the French sociologist Kaufmann's ethnographies of daily life, his study of the conflicting values of modern marriages analyzed through the routines of doing the laundry in a sample of French families (Kaufmann, 1998). Through extensive interviews with wives and husbands about their laundry habits, Kaufmann throws new light on the constant negotiations typical of modern marriages, negotiations about divisions of labor, definitions of love and individual space, as well as changing perceptions of the moral economy of the family.

Similar examples of such a use of back-door entrances to major issues can be found in those studies of nationalism, which do not take ideology or official rhetoric of major institutions as their starting point, but want to understand the power of 'the national' through the modes in which it is anchored and materialized in everyday life. Such studies, for example, Billig (1995), illustrate the powerful ways in which the nation-state has been made visible and tangible in a wealth of everyday situations and settings, and how citizens have been touched by the state.

Analyzing Undercurrents

During the early 2000s, there was a renewed interest in studies of the everyday, often as an interdisciplinary dialogue between anthropologists and sociologists. One reason for this was the wish to develop new theoretical and methodological tools for analyzing the nondiscursive dimensions of social life as well as the interaction with the material world. A good example of this focus is the renewed interest in mundane routines and habits as an often-unconscious undercurrent in everyday life (for an overview, see Shove et al., 2009). Studying everyday routines is methodologically challenging, as they often rest in the body rather than in the conscious mind, naturalized into reflexes. How are routines learned and how are they internalized into implicit knowledge? In what kinds of situations do they surface? What happens when they are contested? Questions like these came to engage many scholars (see the discussion in Ehn and Löfgren, 2010: 71ff.)

Another reason behind this new interest in routines has to do with the fact that their seemingly insignificance or invisibility often hides issues of power, freedom, and control. By looking ethnographically closer at routines, it becomes possible to destabilize the notion that they are about 'just going through the same movements.' The repetitious nature of routines often hides important micro-changes that eventually may transform them into something else, as Tom O'Dell (2006) has pointed out.

Over the last years, the classic discussions of routines and habituation in the works of scholars like Pierre Bourdieu (1977), Michel de Certeau (1984), and Norbert Elias (1939/1978) may be contrasted with some more recent

studies such as those by Ben Highmore (2010), Elizabeth Shove et al. (2007), and Sarah Pink (2012), who have developed a more nuanced understanding of how routines work in everyday life.

Studies like these work as a reminder that the seemingly insignificant may be a good starting point for exploring the workings of society. Studies of everyday life have produced techniques and methods for understanding how a lot of cultural energy may be condensed or crystallized in a trivial situation, an unperceived object, or a prosaic routine. They have also led to a much greater reflexivity about the manners in which the study of the everyday is conditioned by the researcher's own embeddedness in his or her own everyday practices.

Evidence-Based Medicine

Matthias Egger, University of Bern, Bern, Switzerland

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Evidence-based medicine (EbM) was developed in the 1990s and was quickly adopted worldwide. EbM is defined as the integration of current best evidence from patient-centered clinical research, clinical experience, and patient values and preferences in making decisions about the care of individuals. Evidence-based medicine proceeds in four steps: (1) the formulation of a precise clinical question, (2) the identification of the best available evidence, (3) the critical appraisal of the evidence, and (4) its application in clinical practice. Systematic reviews of relevant studies and their statistical synthesis in meta-analysis are important resources for evidence-based health care. Evidence-based medicine has been described as "one of modern medicine's greatest intellectual achievements" but some resent the limitation of the freedom of doctors to treat a patient in the way they believe is best.

Introduction

Evidence-based medicine (EbM) was first proposed as 'a new approach to teaching the practice of medicine' in 1992 (Evidence-Based Medicine Working Group, 1992), but its roots extend back to the 1950s and earlier. The application of epidemiological thinking and methods to study medical practice and health services from the 1950s onwards, pioneered by Alvan Feinstein (1925–2001) and Thomas C. Chalmers (1917–95), which later became known as *Clinical Epidemiology* (Sackett, 1991), the rise of randomized controlled trials to evaluate medical interventions, and the introduction of systematic reviews and meta-analyses in the 1990s were all instrumental. The 1972 book by Archibald Cochrane (1909–88) on *Effectiveness and Efficiency – Random Reflections on Health Services* (Cochrane, 1972) inspired Iain Chalmers and others to set up the *Cochrane Collaboration*, which assists providers, policy makers, and patients by preparing and disseminating systematic reviews of health care interventions. Richard Smith and Drummond Rennie, who were involved as editors of medical journals, have recently created an oral history of EbM on video, with perspectives from individuals who played pivotal roles in its development (Smith and Rennie, 2014).

EbM stands for a practice of medicine that is based both on expert opinion and clinical skills and up-to-date data from relevant patient-oriented research. Proficiency in how to interpret the results from such clinical studies and how to use them for making decisions in the context of the care of an individual patient are as important as background knowledge on pathophysiological mechanisms. David Sackett, who is widely regarded as the 'father of EbM,' and colleagues defined EbM as,

> the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients. The practice of evidence based medicine means integrating individual clinical expertise with the best available external clinical evidence from systematic research.
>
> Sackett et al., 1996

How accurate is exercise electrocardiography in the diagnosis of coronary heart disease? What is the life expectancy of HIV-infected individuals in the era of potent antiretroviral combination therapy? How efficacious is an inhibitor of the BCR-ABL tyrosine kinase in older men with chronic myeloid leukemia? EbM critically evaluates diagnostic and screening tests, prognostic information, and therapeutic interventions to answer these types of questions. To be useful, such research must be based on patient-centered outcomes, i.e., outcomes that people care about, such as survival, physical, and cognitive function, symptoms, and health-related quality of life. The available evidence is then systematically reviewed and, if appropriate, statistically combined in meta-analyses (Egger et al., 2001). The body of data is finally graded in terms of its validity and used in guidelines to inform clinical practice (Guyatt et al., 2008).

Clinical expertise and skills are essential in many areas of clinical practice, for example, when making a diagnosis after careful history taking and clinical examination of the patient, or by integrating the patient's preferences in making decisions about his or her care, based on the experience gained over years of working with patients with similar symptoms and conditions (Straus, 2011). Values and preferences vary widely between patients. They may depend on patients' age and other sociodemographic characteristics, their prior experience with treatments or health outcomes, but also on the methods used to assess preferences (MacLean et al., 2012). **Figure 1** summarizes the three key elements contributing to EbM.

Why Do We Need EbM?

You might ask, haven't doctors always practiced EbM? Perhaps surprisingly, the answer is no: before the advent of EbM the use of critically appraised results from patient-oriented research was less common and less systematic. The opinion of experienced clinicians, based on their authority and status, was often uncritically accepted, even in the absence of good data from clinical research supporting these views. Physicians practiced medicine primarily based on what was taught at medical school, their experience and local habits, leading to striking variations.

Figure 1 Key components of EbM.

Terms like 'expert-based,' 'opinion-based,' or 'eminence-based' medicine are sometimes used to describe this situation. Much emphasis was given to pathophysiological reasoning, data on potential mechanisms and surrogate endpoints.

Surrogate endpoints are measures of intermediate effects of a treatment that correlate with a patient-centered outcome; for example, cardiovascular risk factors such as blood pressure or cholesterol levels, which are associated with cardiovascular disease. The short-term change in a risk factor observed with a drug is then interpreted as if the long-term health benefits corresponding to this change are guaranteed to follow (Fleming and DeMets, 1996). The widespread use in the 1980s of flecanaide, a type-1 antiarrythmic drug, to prevent sudden cardiac deaths is one of many examples where this was erroneously assumed. Sudden deaths are often caused by disturbances of the heart beat (arrhythmia) or cardiac arrest. The risk is higher in people who previously had a heart attack. Many such patients were therefore given flecanaide or similar drugs prophylactically, particularly in the United States. The drugs were effective in suppressing ventricular premature beats (the surrogate endpoint), but a large randomized controlled trial, the Cardiac Arrhythmia Suppression Trial (CAST), showed that total mortality was higher with flecainide than with placebo (Echt et al., 1991).

In his book entitled *Deadly Medicine*, the journalist Thomas Moore argued that "tens of thousands of heart patients died in America's worst drug disaster" (Moore, 1995). Although the accuracy of Moore's figures is disputed, it is clear that many patients were exposed to an increased risk of death before the CAST trial stopped this practice. Other examples of failed surrogate endpoints include tolbutamide and phenformin which lower blood glucose but were associated with a higher risk of death, or fluoride which enhances bone mineral density, but caused more fractures overall (Fleming and DeMets, 1996).

Key Steps

EbM proceeds in four key steps from formulating a clinical problem to solving it based on the best available evidence. These steps are discussed in the following sections.

Formulate Precise Clinical Questions

The formulation of a precise question is key to clarifying the nature of the problem and to avoid getting loss in a huge amount of literature later on. It is helpful to develop the question in terms of the patient group concerned, the intervention (typically drugs or other medical interventions), the comparison (standard care, or no intervention), and the (patient-centered) outcome. The mnemonic *PICO* is often used in this context: *Patient, Intervention, Comparison and Outcome*. For example, an elderly woman who suffered a myocardial infarction 4 years ago reports breathlessness and swollen ankles, i.e., typical signs of heart failure. She has been taking a nonsteroidal anti-inflammatory drug (NSAID) for the past month because of knee pain. A relevant question in this situation might be as follows: In elderly women with a history of coronary heart disease who developed signs of heart failure on NSAIDs, is it sufficient to stop the anti-inflammatory drug? Should drugs against heart failure, for example diuretics, be given immediately? Are diuretics sufficient or should they be combined with other drugs?

Identify the Best Available Evidence

Once the question has been defined the search for relevant literature can start in order to identify the relevant evidence. This is an iterative process which involves the definition of appropriate search terms in electronic databases such as *PubMed* or *Embase*, based on the components of PICO. For example, let's assume our question is whether insulin pumps improve the control of blood glucose and the quality of life in children with type I diabetes, in comparison with daily insulin injections. The search terms will relate to study populations of children with type I diabetes, different types of insulin pumps as the intervention of interest compared to conventional care with daily insulin injections, and outcomes levels of hemoglobin A1c, hypoglycemic episodes and quality of life. We use Boolean operators to combine search terms in the databases: OR to capture several terms for one concept (for example 'insulin infusion system' OR 'insulin pump' OR 'artificial pancreas') and AND to combine the different searches for the components of PICO.

It is of course important to focus on the best possible studies, but which are the best studies? Several systems have been developed to classify studies according to their vulnerability to bias. **Figure 2** shows the *hierarchy of evidence* proposed by the US Agency for Health Care Policy (US Department of Health and Human Services, Public Health Service, Agency Health Care Policy and Research, 1992) to establish causal effects of medical interventions. Among different study designs, randomized controlled trials (RCTs) provide the highest level of evidence: in large trials randomization will ensure that the groups to be compared are similar, thus preventing any distortion of results due to an imbalanced distribution of prognostic factors. Studies that compare patients that received a drug with individuals who received no treatment or another drug are at high risk of bias. People receiving a drug are generally sicker than those who do not, and there are good reasons why one drug and not another is prescribed; reasons that are often associated with the severity and prognosis of the disease. In well-designed cohort studies, case–control studies or

Figure 2 Levels of evidence.

before–after studies such biases can be reduced, but only randomization can guarantee that prognostic factors are balanced between groups. Several RCTs are required to document the consistency of effects in different patient groups and health care settings. They are ideally summarized in systematic reviews and, where appropriate, statistically combined in meta-analyses. Search terms denoting study designs (for example, 'randomized controlled trial' or 'meta-analysis' as publication types in the PubMed database) are therefore often combined with the PICO-related search described above.

Critically Appraise the Evidence

Although we may have focused on the study designs that minimize bias in our search of the literature, we still need to critically appraise the relevant studies one by one in terms of internal and external validity. Internal validity describes the extent to which the results are valid for the patients included, i.e., not distorted by bias or confounding. External validity relates to the extent to which the results can be applied to different patient groups and settings. For example, can the findings from a study done in a University tertiary care clinic be applied to a small district hospital, or to primary care?

Appraising internal validity is a matter of understanding the strengths and limitations of the design, conduct and analysis of a study. Internal validity is a prerequisite for external validity: a flawed study cannot be externally valid. The often incomplete and intransparent reporting of studies is a problem when assessing the internal and external validity of studies. Important methodological details and details on the study population and intervention are often missing from the scholarly articles. In recent years this situation has been addressed by the development of reporting guidelines for different study types. A network to Enhance the QUAlity and Transparency Of health Research (EQUATOR) has built a comprehensive searchable library of reporting guidelines, which is freely available on the web (The EQUATOR Network, 2014).

Bias is a systematic deviation of a study's result from a true value. Typically, bias is introduced during the design or implementation of a study and cannot be remedied later. Bias arises from flawed information or flawed patient selection so that associations are found that do not exist in reality. Confounding produces relations that are real, but do not reflect causal relationships because of some other factor that is not accounted for. Bias and confounding need to be distinguished from random error, a deviation from a true value caused by statistical fluctuations in the data (Vandenbroucke et al., 2007).

Many possible sources of bias have been described and a variety of terms are used. Two simple categories are helpful: information bias and selection bias (Vandenbroucke et al., 2007). Information bias occurs when systematic differences in the completeness or the accuracy of data distort results. Selection bias is introduced if the groups that are being compared in a study are not representative of those the results will be applied to. For example, in clinical trials attrition due to loss of participants during the study may introduce selection bias: those who stay in the study often differ from those who drop out, for example with respect to severity of disease, or side effects of drugs. The data available at the end of the study may thus have become biased. Confounding means confusion of effects. A study might seem to show either an association or no association between an exposure and the risk of a disease. In reality, the seeming association or lack of association is due to another factor that increases the risk of the disease but that is also associated with the exposure. The other factor is called the confounding factor or confounder. Confounding thus gives a wrong assessment of the potential 'causal' association of an exposure. For example, a study might find that yellow fingers increase the risk of developing lung cancer. The confounding factor here is of course heavy smoking, which makes your fingers go yellow and also increases your risk of lung cancer (Smith and Phillips, 1992). Proper randomization of patients to comparison groups in clinical trials prevents confounding. In other studies confounders can be taken into account in the analysis, but results might still be distorted by residual confounding (the confounding that remains after attempts to control for it).

The Cochrane Collaboration developed a helpful 'Risk of Bias' tool to assess the methodological quality of RCTs (Higgins et al., 2011). Useful checklists for other types of studies are available from the Critical Appraisal Skills Program in the United Kingdom (Critical Appraisal Skills Program (CASP), 2014).

Apply the Evidence in Clinical Practice

As Archibald Cochrane observed in 1972, "Between measurements based on RCTs and benefit … in the community there is a gulf which has much been under-estimated" (Cochrane, 1972). Unlike the assessment of the internal validity of a study, there are no accepted guidelines on how the external validity, generalizability, or applicability of studies should be assessed. Assessing external validity is a matter of judgment, based on a careful assessment of the setting of trials (for example, the level of care or the type of health care system), the selection of patients (the eligibility and exclusion criteria), the characteristics of the patients included in the study (for example, the severity of disease), the difference between the trial protocol and routine practice (for example, the timing and dose of the drug), and other factors (Rothwell, 2005). The consistency or inconsistency of results across different studies is

an important consideration, which supports or questions the generalizability of results to routine clinical practice.

Clinical decisions can then be made, taking into account the values or preferences of patients. The critically appraised body of evidence also forms the basis for developing guidelines and recommendations. The GRADE (Grading of Recommendations Assessment, Development and Evaluation) system is often used for this purpose (Guyatt et al., 2008). GRADE is a system for rating the quality of the evidence and the strength of recommendations in guidelines, which is increasingly adopted by organizations worldwide, including the World Health Organization.

Resources and Tools for Evidence-Based Medicine

Systematic Reviews and Meta-analyses

Systematic reviews and meta-analyses are an important source of evidence for EbM. Systematic reviews are 'studies of studies.' Like any study of patients or healthy volunteers, they are done using a systematic approach to minimize bias and random error, which is described in a study protocol. The protocol details the eligibility criteria for studies to be included and describes the search strategy to identify potentially eligible studies, and their critical appraisal. Systematic reviews may, or may not, include meta-analysis, a statistical combination of results from several studies to produce a single estimate of the effect of an intervention. Systematic reviews allow for a more objective appraisal of the evidence than traditional, narrative reviews and might help to resolve uncertainty and identify areas where further studies are needed. Meta-analysis will enhance the precision of estimates of intervention effects, leading to reduced probability of false negative results, and potentially to a timelier introduction of effective interventions. Methods for analyzing the evidence that is available on the benefits and harms for several drugs or an entire class of drugs (for example, NSAIDs) have also become available. Such *network meta-analyses* simultaneously analyze direct evidence from trials comparing two drugs (for example, A vs C, or B vs C), and indirect evidence (A vs B) and are increasingly used in *comparative effectiveness research*, which aims to provide evidence on the benefits and harms of different treatment options (Cipriani et al., 2013).

The Cochrane Library

The *Cochrane Library*, the main product of the Cochrane Collaboration, is a prominent source of systematic reviews of health care interventions ('Cochrane reviews'). At the time of writing, the database included over 5000 systematic reviews as well as a large collection of randomized controlled trials. The logo of the Cochrane Collaboration (**Figure 3**) shows a meta-analysis of seven RCTs of a short, inexpensive course of a corticosteroid given to women about to give birth too early. Each horizontal line represents the results of one trial (the shorter the line, the more certain the result); and the diamond represents their combined results. The position of the diamond to the left of the vertical line indicates that the treatment studied is beneficial. Indeed, this treatment reduces the odds of the babies of these women dying from the complications of immaturity by 30–50%. As no systematic review and meta-analysis of these trials had been published until 1989, most obstetricians had not realized that the treatment was so effective, and many premature babies have probably suffered and died unnecessarily (The Cochrane Collaboration, 2014).

Figure 3 The logo of the Cochrane Collaboration.

The Campbell Collaboration, named after Donald Campbell (1916–96), an American psychologist and thinker, was set up to prepare systematic reviews of high-quality research on effective methods and interventions in the fields of social welfare and social work, education and learning, and crime and delinquency (The Campbell Collaboration, 2014).

Other Resources

Numerous resources on evidence-based health care are available, including books, databases offering online access to medical evidence, journals dedicated to EbM, and resources for patients. Applications customized for use on mobile devices are also increasingly available. For example, the *National Institute for Health and Care Excellence* (NICE) in the United Kingdom provides primary care practitioners with summaries of the current evidence base and practical guidance in respect of over 300 conditions relevant to primary care. Produced by the BMJ Group, *Best Practice* summarizes the evidence from relevant systematic reviews, guidelines on the diagnosis, prognosis, treatment, and prevention for a large number of clinical specialties, ranging from psychiatry to cardiac surgery. The *Physiotherapy Evidence Database* (PEDro) provides access to over 27 000 RCTs, systematic reviews, and clinical practice guidelines in physiotherapy. The website of the Cochrane Collaboration provides an excellent 'webliography' of EbM resources (The Cochrane Collaboration, 2014).

Critique, Limitations, and Debates

EbM has recently been described as "one of modern medicine's greatest intellectual achievements" (Smith and Rennie, 2014), but its reception was mixed in the 1990s and critical views continue to be voiced. Sackett and colleagues addressed some of points raised in an editorial with the title "Evidence based

medicine: what it is and what isn't" (Sackett et al., 1996): the pronounced variations observed in clinical practice demonstrated that not 'everyone is already doing it' and the experience from frontline medicine documented the feasibility of EbM. Furthermore, Sackett and colleagues argued that EbM is not 'cookbook' medicine because it integrates evidence from patient-centered research with expertise, experience, and patient choice, and that EbM is not restricted to evidence from RCTs but considers other studies to answer relevant questions, for example, cohort studies on prognosis (Sackett et al., 1996).

In his oral history of EbM, Iain Chalmers expressed anger that in medical school he was "not given the tools to find out what worked" in medical practice. Many of his generation share this anger: the role of EbM in medical education cannot be overestimated. However, medicine is not an exact science and neither is EbM: assessing the quality of the evidence and applying the 'best evidence' from clinical research to an individual patient is to some extent subjective, but this is not always fully appreciated by EbM enthusiasts. Ironically, the properties of some of the tools promoted for EbM have not been well evaluated, for example, the GRADE system, and others are known to produce misleading results in some situations, for example, meta-analysis (Egger and Smith, 1995). Some resent that the freedom to treat a patient in the way the doctor believes is best has been limited by EbM, and argue that "patients are individuals, and need individual treatment" (Hampton, 2002). This view will likely gain momentum with the advent of personalized medicine, where treatments are tailored to the individual's genomic makeup. The potential of EbM will strongly depend on the health service and the values and attitudes of the public, but EbM is often discussed in isolation. For example, in the United States or Switzerland fee for service payments can create strong incentives to adopt interventions that are well reimbursed, even if the evidence base is poor. Finally, sometimes you meet colleagues, perhaps on guidelines committees, who appear to practice EbM as a religion and are at risk of losing sight of common sense. This sentiment was expressed in an entertaining article on the efficacy of parachutes to prevent 'death related to gravitational challenge,' which ended with the recommendation that the most radical protagonists of EbM should participate in a double blind, randomized, placebo controlled, crossover trial of the parachute (Smith and Pell, 2003). While such a trial should probably be avoided, it is clear that much has been achieved and much remains to be done to further develop the principles and practice of EbM and to better understand its potentials and limitations.

Evidence-Based Practice

Jeremy Steglitz, Jennifer L Warnick, Sara A Hoffman, Winter Johnston, and Bonnie Spring, Northwestern University, Chicago, IL, USA

Abstract

Evidence-based practice (EBP) is an approach that aims to improve the process through which high-quality scientific research evidence can be obtained and translated into the best practical decisions to improve health. The interprofessional model of EBP emphasizes shared decision-making within the context of the most important advances of the various health professions. The model depicts three data streams that are integrated in the decision-making process: evidence, resources, and patient characteristics. Health professionals can play several different roles in the EBP process, including primary researchers, systematic reviewers, and clinicians. Carrying out the EBP process involves five steps, including Ask, Acquire, Appraise, Apply, and Analyze and Adjust. A new generation of research designs, such as the Sequential Multiphased Adaptive Randomized Trial, has been put forward to develop treatment algorithms that optimally capture the Apply, Analyze and Adjust steps of the EBP process.

Definition

Evidence-based practice (EBP) is an approach that aims to improve the process through which high-quality scientific research evidence can be obtained and translated into the best practical decisions to improve health. Research findings derived from the systematic collection of data through observation and experiment, as well as the formulation of questions and testing of hypotheses comprise the evidence supporting practice. EBP harmonizes the standards used to conduct, report, evaluate, and distribute research results so as to increase their application to practice and policy. EBP also involves the use of conscientious and explicit decision-making that integrates consideration of the best available research evidence, client characteristics (including preferences), and resources. Best available research is defined as contextually relevant and best in quality, according to consensually accepted scientific standards for different types of questions. Practical decisions relevant to EBP often involve the selection of an assessment or intervention. While professionals practicing evidence-based medicine (EBM) often need to choose among treatments involving drugs or devices, those practicing evidence-based behavioral medicine (EBBM) usually make selections among nondrug and nondevice behavioral or psychosocial interventions.

History of EBP

The origins of EBP are usually dated to 1910, when the American Medical Association and the Carnegie Foundation commissioned Abraham Flexner, a research scholar at the Carnegie Foundation for the Advancement of Teaching, to survey American and Canadian medical schools. The Flexner Report, as it was called, represented a major effort to reform medical education by placing it on a scientific foundation. Flexner surveyed 155 medical schools and severely criticized the training offered by many of them. His findings revealed that most medical schools offered lax clinical training, a curriculum not based on science, and a motivation that promoted profit rather than public service (Flexner, 1910). The Flexner Report established an educational quality standard that many of the existing medical schools could not meet. Therefore, more than half of all medical schools closed by 1935 (Beck, 2004). This report is widely regarded as the start of the EBM movement.

A second main catalyst for the EBM movement came from Archibald Cochrane, a British epidemiologist who aimed to establish a rational, systematic basis for determining what treatments should be covered by health care (Cochrane, 1972). Cochrane argued that because resources for health care are inevitably limited, it is essential that scarce dollars be allocated only for procedures of demonstrated worth. He argued that randomized controlled trials (RCTs) offer the most unbiased, reliable method to evaluate the effectiveness of treatments, warranting their placement at the top of a hierarchy of evidence. Accordingly, findings from high-quality RCTs are given greater credence than those from observational studies, case studies, and expert opinion when determining whether a treatment is effective. Followers of Cochrane's work subsequently established the Cochrane Collaboration (www.cochrane.org), a worldwide network that tracks, critically appraises, and synthesizes results of RCTs, publishing their findings online.

In the 1990s, a group of clinical epidemiologists working at Canada's McMaster University under the direction of David Sackett and Gordon Guyatt spearheaded the third initiative that catalyzed the EBM movement. This group's mission was to close the research-to-practice gap by encouraging physicians to engage in lifelong learning about new research findings (Sackett and Rosenberg, 1995a,b). The McMaster group was motivated by evidence that health professionals primarily implement treatment practices learned during training but neglect new and often more efficacious treatments that emerged subsequently (Isaacs and Fitzgerald, 1999). To change this habit, the McMaster group developed methods for health professionals to find, assess, and apply research results. However, the group encountered resistance from health professionals who believed that exclusive practice based upon

 http://dx.doi.org/10.1016/B978-0-08-097086-8.10540-9

research findings devalued clinical expertise and experience (Haynes et al., 1996). To overcome this perceived slight against practicing clinicians, Guyatt et al. (1992) renamed the approach 'evidence-based medicine' in place of 'scientific medicine.' In this newest model, EBM was presented as an approach that tied together and utilized research, patient characteristics, and expertise to formulate best treatment practice, as opposed to relying solely on research findings (Haynes et al., 1996; Sackett et al., 1996).

EBM to EBBM

To evaluate interventions besides drugs or devices, health professionals in the behavioral sciences also needed a standard to evaluate behavioral treatments. The first entity to take on this task of conceptualizing EBBM was the Society of Behavioral Medicine's EBBM Committee. Established in 2000 with support from the National Institutes of Health (NIH) Office of Behavioral and Social Science Research (OBSSR) under Acting Director, Peter Kaufmann, the first EBBM Committee, first chaired by Karina Davidson, defined its scope to include behavioral interventions that prevent disease, promote health and adherence to treatment, or change biological determinants of behavioral conditions (Davidson et al., 2003). Initially, this committee familiarized behavioral medicine researchers with the Consolidated Standards of Reporting Trials (CONSORT) guidelines that encourage comprehensive, transparent reporting of RCTs in medical journals (Schulz et al., 2010). This effort was one of many that led behavioral science journals to adopt the CONSORT guidelines for publishing clinical trials. Among the first behavioral science journals to adopt CONSORT were *Annals of Behavioral Medicine*, *Health Psychology*, *International Journal of Behavioral Medicine*, and the *Journal of Consulting and Clinical Psychology*. The EBBM committee also addressed other weaknesses in the quality of behavioral clinical trials, especially with regard to the analytic approach. Numerous behavioral treatment trials were found to have analyzed data only from those who completed the final assessment in a clinical trial or who experienced a full dose of treatment (Pagoto et al., 2009; Spring et al., 2007). Since then, use of the intent-to-treat policy has increasingly become normative in behavioral science, such that data from all randomized participants are included in study analyses according to the condition to which they were assigned.

EBBM Evolves to EBBP, and Then to EBP

By 2006, the US health-care crisis was in full swing. With it came the need for a better, more integrated system of care that addressed mental as well as physical health for the sick and prevention for the well. The only way to accomplish all of this was by the coordinated efforts of an interprofessional team. It became clear that the EBBM approach needed to be upgraded to include all health professionals. Thus, OBSSR sponsored the Council on Evidence-Based Behavioral Practice (EBBP), chaired by Bonnie Spring, and its scientific and clinician advisory boards. The composition of the Council and the Boards was determinedly interprofessional, combining representatives from medicine, nursing, psychology, social work, public health, and information sciences (www.ebbp.org). The Council's first task was to formulate a conceptual model that could accommodate the diverse historic traditions as well as the individual- and population-level behavioral interventions that different health professions implement.

Initially, the conceptual model for EBM emphasized only a single parameter: research (Sackett et al., 1996). Later, the EBM model expanded to include other considerations such as clinical experience and specific patient needs. The EBM definition stated that: "evidence-based medicine requires the integration of the best research evidence with clinical expertise and the patient's unique values and circumstances" (Strauss et al., 2005). EBBM expanded upon EBM by adding nondrug, nondevice treatments. EBBP went one step further by consolidating across different disciplinary frameworks for EBP. The goal was to develop a conceptual model that could be shared by a more diverse interprofessional health-care team, whose members all require core competency in EBP (Greiner and Knebel, 2003). This shared EBP model supports jointly held vocabulary, foundational assumptions, and practice principles that unite the team of professionals in medicine, nursing, psychology, social work, public policy, and information sciences. A unified EBP eliminates the need to have separate models for different disciplines (Satterfield et al., 2009; Spring and Hitchcock, 2009).

Interprofessional Model of EBP

The interprofessional model of EBP (**Figure 1**) emphasizes shared decision-making within the context of the most important advances of the various health professions, including those mentioned above. The model depicts three data streams that are integrated in the decision-making process: evidence, resources, and patient characteristics. The interprofessional EBP model is grounded in an ecological framework that emphasizes the importance of considering environmental and organizational spheres when conceptualizing the problem and designing a course of treatment.

Best Research Evidence

Evidence refers to research findings from the systematic collection of data through observation and experiment grounded in

Figure 1 Interprofessional model of EBP.

the formulation of questions and hypothesis testing. That, which is deemed best research evidence is contingent on the particular question that needs to be addressed (Sackett and Wennberg, 1997). A question concerning etiology or prognosis, for example, is optimally answered through a longitudinal cohort research study design. On the other hand, a question about efficacy and effectiveness of treatments benefits from an RCT that is less susceptible to bias and error. Treatment-based questions can be addressed particularly well with the systematic review, which synthesizes the findings from multiple RCTs (Oxford Center for Evidence-Based Medicine, 2001). Recent interest in personalized care has generated interest in contextualized research evidence that is uniquely applicable to a particular patient and practice context (Weaver et al., 2005; Westfall et al., 2007). This has led to a resurgence of interest in the single-case experimental design (Dallery et al., 2013), which some representations of the evidence hierarchy place at the top of the evidence pyramid (Figure 2).

Resources

Resources refer to the skills and infrastructure that are required to provide EBPs. Resources needed to deliver treatments include physical, technological, financial, and personnel assets (e.g., office space, technological support, insurance reimbursement, and expert health professionals trained in an evidence-based treatment). Additional resources may include institutional endorsement by higher administration and agreement from other system components to make a treatment available.

The interprofessional EBP model breaks down clinician expertise into four categories of skill: assessment skills, EBP process skills, communication and collaboration skills, and engagement and intervention skills.

1. *Assessment skills* refer to the appraisal of patient characteristics, problems, values and expectations, and environmental factors.
2. *EBP process skills* are defined by competency in carrying out the steps of the EBP process: ask well-formulated questions, acquire best available research evidence, appraise quality and relevance of evidence, apply evidence, analyze change, and adjust treatment accordingly.

Figure 2 Evidence hierarchy.

3. *Communication and collaboration skills* involve the capacity to convey information clearly and appropriately. Further, they include the ability to listen, observe, adjust, and negotiate in order to achieve an agreed-upon treatment plan.
4. *Engagement and intervention skills* entail proficiency at motivating interest, constructive involvement, and positive change from individuals, groups, organizations, communities, and other entities affected by health decisions.

A recent development in EBP is resource-sensitive practice guidelines that review evidence for appropriate practice recommendations given an available level of resources (cf Fried and Krabshuis, 2008). Resource-sensitive guidelines enable decision-makers to appraise the level of intervention intensity that optimizes the available degree of accessible infrastructure, human capital, and financial resources.

Patient Characteristics

Patient characteristics are a key set of contextualizing factors. They include individual attributes such as state and trait variation in condition, needs, history of treatment response, values, and preferences that all influence whether a treatment is well matched to a particular patient. When deciding whether available research evidence is relevant to a given individual, health professionals need to assess the comparability between patient and study population. Tailoring surface aspects of the treatment can enhance its acceptability to the patient, so long as modifications do not stray so far from fidelity to core treatment elements that treatment loses its effectiveness (National Cancer Institute, 2006).

Patient preferences are a singular type of contextualizing variable. Although patient preferences are a particularly vital part of shared decision-making, they are the least developed aspect of the EBP model. Shared decision-making is grounded in the empowering of patients to self-manage their health and health care. Two preconditions for shared decision-making exist. The first is departure from a paternalistic model of care in which the clinician makes decisions on the patient's behalf. The second is adoption of a culturally informed model of care, whereby health professionals assist patients in clarifying their own values and treatment preferences.

Health Professionals' Roles in EBP

Health professionals can play several different roles in the EBP process (Figure 3).

First, they can be primary researchers who directly contribute to forming the evidence base. Primary researchers not only develop new treatments, but also design, conduct, analyze, and report research that evaluates the efficacy and effectiveness of interventions. Ideally, they will conduct RCTs to evaluate whether a treatment works. If, however, time and resources are insufficient to conduct an RCT, primary researchers may use alternative designs such as an intermittent time series.

A second role that health professionals can play is that of systematic reviewers, whereby they act as evidence synthesizers. They aggregate primary research to analyze and interpret synthesized findings that can be accessed and used efficiently

Figure 3 Roles of health professionals in the EBP model.

by health professionals. The role of the systematic reviewer is particularly critical within the EBP framework due both to the rapid proliferation of the scientific literature and health professionals' limited time to remain comprehensively informed of new research. The EBP system is made possible because systematic reviewers collect and analyze the full body of new and old studies that address clinically relevant questions. Systematic reviewers then disseminate their findings to health professionals in the form of succinct summaries that offer EBP recommendations for practicing clinicians.

Systematic review methodology includes a series of steps, including the formulation of a structured PICOT question that specifies the target population (P), candidate intervention (I) to be evaluated, comparator (C) intervention, patient outcome (O) of interest, and over what time frame (T) the outcome is to be assessed. After formulating the PICOT question, the systematic reviewer develops a comprehensive and unbiased protocol whose objective is to identify research that addresses the question. Once the relevant studies have been acquired, a decision about whether to include them in the review can be made relative to protocol entry and exclusion criteria. Included studies are then critically appraised for methodological quality, and their data extracted and synthesized to reach an answer to the question at hand. Synthesis is sometimes performed quantitatively, if the included interventions and study designs are sufficiently homogeneous; alternatively, synthesis can be performed qualitatively. Increasingly, systematic reviews constitute a requisite basis for EBP guidelines and health policies.

The third role that health professionals can play is that of the clinician. Assuming one of the most complex and challenging roles in EBP, the clinician extracts and uses data from each of the three EBP circles. Unlike the primary researcher or systematic reviewer, the clinician interacts directly with the two circles of the EBP model that concern patient characteristics and resource considerations. Additionally, health professionals are research consumers in that they access research evidence and assess its quality and relevance for the patient and context at hand. Secondary, synthesized, critically preappraised evidence sources, such as systematic reviews or EBP guidelines on www.guidelines.gov are intentionally designed to give the busy health professional a way to efficiently find the best research-tested answer to the most commonly asked practice questions. In some circumstances, however, available systematic reviews and treatment guidelines may not provide an answer, requiring the clinician to search the primary literature to identify relevant research. To enhance the simplicity of the clinician's complex job, the five-step EBP process delineates a recommended series of steps that health professionals can follow to address each of the three circles of the EBP model.

The Five Steps of EBP

Carrying out the EBP process involves five steps (Figure 4):

Step 1: Ask patient-oriented, well-formulated questions about the health status and contexts of individuals, communities, or populations.

Step 2: Acquire the best available evidence to answer the questions.

Step 3: Appraise the evidence critically for validity and applicability to the problem at hand.

Step 4: Apply the evidence by engaging in collaborative health decision-making with the affected individual(s) and/or group(s). Implement the health practice. Appropriate decision-making integrates the context, values, and preferences of the individual, community, or population. It also integrates available resources, including professional expertise.

Step 5: Analyze the new health practice and adjust practice accordingly. Evaluate implications for future decision-making, disseminate the results, and identify new informational needs.

Figure 4 The 5As approach of EBP.

Competencies

Ask

EBP health professionals ask important, practice-relevant questions. They know how to translate their information needs into well-formulated, answerable questions. Further, they differentiate among various types of practical questions, including assessment, intervention, prognosis, harm, cost-effectiveness, and seek the best type(s) of evidence to answer each kind of question.

Acquire

EBP health professionals answer their questions by efficiently and effectively searching for the best available evidence. Specifically, EBP health professionals understand how to seek answers to their questions by accessing clinical guidelines and systematic reviews of research on health procedures. They know the difference between primary and secondary (synthesized) research evidence, and can translate questions into efficient search plans. They can use available technology and information systems to stay up-to-date regarding research relevant to their questions.

Appraise

EBP health professionals critically appraise evidence based on its quality and applicability to the specific population and circumstances at hand. When evaluating research on interventions, it is important to consider both internal and external validity. Internal validity represents the extent to which research was designed and conducted in a way that enables change to be causally attributed to the intervention as opposed to extraneous variables. External validity reflects whether characteristics of the research population or intervention context can be generalized to the current population, interventionist, or circumstances. Applicability refers to the clinician's judgment vis-à-vis the fit of the evidence with the circumstances.

In terms of specific competencies, EBP health professionals know the strengths and weaknesses of different kinds of research evidence for answering different kinds of health questions. They can evaluate the quality and strength of primary research evidence based on study design and execution. They understand how to synthesize research evidence and how to evaluate the quality and strength of evidence in systematic reviews and practice guidelines. They can identify gaps in evidence that suggest future research. Finally, they evaluate the applicability of the evidence for a particular individual, community, or population.

Apply

Finding the best available research evidence is one thing. Applying it is more complex in EBP, because it requires shared decision-making between health professionals and those affected by an intervention. The aim of the shared decision-making is to arrive at an action plan that balances the applicable evidence, the resources available to implement the best practice, and how the values and preferences of those affected influence the acceptability of the practice.

Analyze and Adjust

EBP health professionals participate in continuous quality improvement. After initiating an intervention that aggregate research suggests is evidence based, the clinician analyzes change and adjusts intervention accordingly. As such, the adaptation of interventions to changing individuals in changing contexts over time is at the core of EBP's transition between the Apply and the Analyze and Adjust. In other words, one initially applies the best 'one size fits all' treatment based on systematic review or aggregate evidence. Subsequently, the adaptation of treatment becomes individualized based on the person's own unique response to the sequence of offered treatments.

Methodological and Practical Challenges

Despite the past decades' great strides toward acceptance and full implementation of EBP, continued *barriers* remain. Rigorously designed research studies are expensive and take time to complete. Often, research findings are simply lacking or insufficient to provide a basis for policy and practice decisions. Gaps in the existing evidence base are especially noteworthy in areas of nondrug treatment interventions and preventive care (Maciosek et al., 2006; Moyer et al., 2005). The U.S. Preventive Services Task Force (USPSTF) was created by the U.S. Department of Health and Human Services in 1984 to address this challenge. *The Guide to Clinical Preventive Services*, which appraises systematic reviews of research graded on its evidence quality was created to allow governing bodies to identify effective evidence-based preventive services (Woolf and Atkins, 2001). The evidence reviewed in the current *Guide* provides the basis for all preventive services mandated by the Affordable Care Act to be covered by insurance without copays. Even so, the evidence about many preventive care practices earns a grade of 'i' for insufficient evidence. As such, the state of the science too often fails to accommodate the demands of policy-makers and health professionals.

Some have gone so far as to challenge the utility and relevance of RCTs as the gold standard research design for evaluating intervention effectiveness. Beyond the expense and duration of RCTs, other criticisms allege an overemphasis on internal validity (freedom from bias) over external validity (sample representativeness, generalizability) (Altman et al., 2001). Other challenges are that RCT designs are sometimes not feasible to implement when, for example, policy-makers or communities decline to accept potential random assignment to a control condition.

Another ongoing tension is that some clinicians chafe under the perceived restrictions that EBP imposes on professional autonomy. While they may appreciate research-tested practices as useful tools, they regard treatment as something of an art form and prefer being given the creative license to try out and develop novel treatment tactics. Additionally, health professionals may lack training in EBP. Although many training programs train students in the use of specific evidence-based treatments, few educate students on the EBP process and steps (Gambrill, 2007a). Discussions are just beginning regarding the best timing and configuration for EBP in the training curriculum (Jenson, 2007) and optimal teaching techniques (Gambrill, 2007b; Sackett et al., 2000).

Emerging Directions

The methods and standards of EBP are now given in health care. Establishing and disseminating an evidence base for behavioral treatments alongside medical treatments is necessary to make them accessible to patients. Providing access is, in turn, essential to achieve patient-centered care because a majority of patients express a preference for behavioral over medical treatments (e.g., Raue and Schulberg, 2007). Systematic reviews and treatment guidelines that include behavioral treatments are needed, particularly because most health insurers now require these EBP components as prerequisites for treatments to become covered practices.

Currently, most evidence-based behavioral treatments resemble evidence-based medical treatments in taking the form of a single, best 'one size fits all' intervention. However, few clinicians believe that one-size treatment fits all. More often clinicians practice by applying a sequence of interventions that they adapt over time depending upon the patient's response. A common protocol is to begin with a best modal practice, evaluate response, and then adapt or change treatment in the case of insufficient response or nonresponse. The sequence of decision rules about how to titrate and adjust treatment contingent upon patient response has been called a treatment algorithm or operational guideline. The algorithm represents a strategy that links together particular treatments that have research support, a strategy about what treatment should be tried first, and a set of tactics or decision rules about what treatment to try next in the case of treatment failure. Like a specific treatment, an algorithm that links together a sequence of research-tested interventions can itself be tested and proven by research to be an efficacious strategy, as compared to a fixed treatment or an alternative treatment algorithm. An example of adaptive treatments that showed efficacy in clinical trials is the Action to Control Cardiovascular Risk in Diabetes trial (e.g., Sullivan et al., 2013). Moreover, once validated, such operational treatment guidelines can be programmed into electronic health records or mobile devices to provide guidance and decision support to clinicians about how to choose the next step in treatment. Approaches like the operational guideline capture both the Apply and the Analyze and Adjust steps of the EBP process. A new generation of research designs, such as the Sequential MultiPhased Adaptive Randomized Trial (SMART) has been put forward to develop such treatment algorithms (e.g., Almirall et al., 2012). We expect these new adaptive interventions to become the EBP wave of the future.

Abstract

Efficacious, effective, and efficient psychiatric treatments are needed to reduce the burden of mental disorders. Evidence-based psychiatry is the process that facilitates the translation of research from the bench to the bedside. The 'evidence' in evidence-based psychiatry is graded according to a hierarchy. Randomized controlled trial(s) are considered to be at the apex of this hierarchy. Most randomized controlled trials use categorical disorders as their primary outcome variable but categorical disorders have limited validity. Pragmatic approaches to improving the 'evidence' in evidence-based psychiatry by accounting for the nature of mental disorders are, therefore, needed and are described herein.

One in two adults will experience a mental disorder in their lives and most of these adults will experience more than one mental disorder (Teesson et al., 2009). As well as being common in the community, mental disorders are highly burdensome (Murray et al., 2013). With the purpose of averting this burden, some governments spend billions of dollars annually on mental health services (Australian Institute of Health and Welfare, 2012). The development and implementation of efficacious, effective, and efficient psychiatric treatments are therefore important public health issues.

Researchers are responsible for establishing treatment efficacy. This is achieved by developing and refining treatment protocols and evaluating treatment outcomes in relation to a null or an active comparator. Mental health practitioners are responsible for providing efficacious treatments to their patients and when mental health professionals use these treatments and achieve comparable outcomes to efficacious studies, these treatments are said to be effective. Governments have limited funds and it is, therefore, ideal that the most efficient treatments are funded, that is, treatments that produce the greatest health benefits for the least government dollars should be funded. This process of translating empirical research from the bench to the bedside is the primary goal of evidence-based psychiatry. This goal is achieved when mental health practitioners make "conscientious, explicit and judicious use of the current best evidence in making decisions about the care of individual patients" (Sackett et al., 1996).

The 'evidence' in evidence-based psychiatry is a graduated construct, the degree of which can be gauged by mental health professionals in relation to the following hierarchy (Geddes and Harrison, 1997; **Table 1**).

When evaluating the degree or quality of evidence in favor of a respective treatment, mental health professionals should prefer data from higher ranked methods over data from lower ranked methods. Data from lower ranked methods can, however, inform clinical decision making when data from higher order methods are unavailable (Geddes and Harrison, 1997). The 'evidence' in evidence-based psychiatry is therefore the sum of the quantitative data from empirical evaluations of respective treatments preferably from the synthesis of multiple randomized controlled trials (Möller, 2009). Psychiatry as a science has much to benefit from employing evidence-based principles. Evidence-based psychiatry holds promise of better health outcomes for patients, legitimizes the treatment protocols that mental health professionals choose, and that governments fund on the basis of quantifiable data that can be disproven using scientific method rather than personal opinion or political agendas.

Despite the potential benefits of evidence-based psychiatry for patients, mental health professionals, and governments, evidence-based psychiatry has been criticized on a number of grounds. Most critiques concern the treatment of randomized controlled trial(s) as the 'best' evidence for preferring particular psychiatric interventions. Experts have suggested, for instance, that it is difficult to generalize the results of randomized controlled trials to the complexities of psychiatric practice, that meta-analyses of multiple trials can bias results, that evidence-based psychiatry does not reflect clinical decision making accurately and that relying heavily on quantitative data minimizes the importance of professional expertise in the diagnosis and treatment of psychiatric disorders (Gupta, 2007; Maier, 2006).

The most evidence-based criticism of evidence-based psychiatry concerns the validity of psychiatric disorders and the use of these disorders as the primary outcome measures in randomized controlled trials. The international psychiatric classifications – the *Diagnostic and Statistical Manual for Mental Disorders-5* (DSM) and the *International Classification of Diseases-10* (ICD) – primarily use a categorical approach to defining

Table 1 Hierarchy of evidence in evidence-based psychiatry

Evidence from a meta-analysis of randomized controlled trials
Evidence from at least one randomized controlled trials
Evidence from at least one controlled study without randomization
Evidence from at least one other type of quasiexperimental study
Evidence from nonexperimental descriptive studies, such as comparative studies, correlation studies and case-control studies
Evidence from expert committee reports or opinions and/or clinical experience of respected authorities

Reproduced from Geddes, J.R., Harrison, P.J., 1997. Closing the gap between research and practice. British Journal of Psychiatry 171, 220–225.

mental disorders. Lists of symptoms and symptom thresholds (e.g., the number and/or combination of symptoms) are used to distinguish between categorically distinct cases of specific mental disorders (e.g., a patient has disorder X but not disorder Y) and to distinguish between cases and noncases of disorder (e.g., a patient has disorder X or they do not). As a result of this categorical approach to classification, randomized controlled trials tend to focus on whether the treatment under trial significantly reduces the number of patients who meet diagnostic criteria for a disorder. This approach to measuring clinical change assumes that there is a group of patients who each meet criteria for the same disorder that these patients experience the disorder in the same way and will therefore respond to treatment in a uniform manner. There are robust data that show that these assumptions are incorrect. The DSM and ICD disorder classifications do not identify mutually exclusive groups of patients. Many of the specifically defined mental disorders share common risk factors and clinical correlates. Moreover, mental disorders are not experienced uniformly. People experience mental disorders to different degrees and in different ways. The inaccurate assumptions that form the basis of most randomized controlled trials therefore threaten the validity of relying on randomized controlled trial data pursuant to the evidence-based psychiatry principles.

Although the validity of psychiatric disorders is a real methodological limitation of most randomized controlled trials and consequently, a limitation of evidence-based psychiatry, the alternative to evidence-based psychiatry is clinical decision making and a mental health system that are uninformed by empirical data. The latter has a significant likelihood of resulting in poor treatment outcomes for patients, bringing the field of psychiatry into disrepute and a mental health system funded based solely on political agendas. This alternative to evidence-based psychiatry is unacceptable. Pragmatic approaches for improving the design of randomized controlled trials in light of the nature of mental disorders are therefore needed. Herein the risk factors and clinical correlates shared by many of the specifically defined mental disorders and the different ways that people experience mental disorders are reviewed. Following on from this discussion, practical ways of accounting for the nature of mental disorders in the design of randomized controlled trials are detailed. These methods are presented as tangible ways of improving the 'evidence' in evidence-based psychiatry.

Many Mental Disorders Share Risk Factors and Clinical Correlates

The notion that the international psychiatric classifications carve nature at its joints and identify discrete disease entities that respond differentially to specific treatments is false (Kendell and Jablensky, 2003). The common mental disorders (e.g., anxiety, depression, conduct, and substance-related disorders) cooccur more often than would be expected by chance (Teesson et al., 2009). This pattern of cooccurrence suggests that these disorders are different manifestations of common underlying liabilities. Indeed, internalizing and externalizing liabilities explain the development and maintenance (Kessler et al., 2011), and the phenotypic and genotypic covariation of the anxiety and unipolar mood disorders, and the substance-related and antisocial disorders, respectively (Andrews et al., 2009; Goldberg et al., 2009; Kendler et al., 2003; Krueger and Markon, 2006). This internalizing–externalizing structure of common mental illness has been replicated across age groups (Fergusson et al., 2011; Lahey et al., 2008; Laurens et al., 2012), ethnicities (Eaton et al., 2012), and countries (Krueger et al., 2003; Slade and Watson, 2006). The internalizing–externalizing model of the occurrence of the common mental disorders has also been extended to explain the occurrence of psychotic-like experiences with a third distinct but correlated factor explaining the cooccurrence of psychotic-like experiences in adults (Wright et al., 2013) and in children (Laurens et al., 2012).

People Experience Mental Illness to Different Degrees

Sadness and anxiety are normal reactions to situational triggers. Although everyone experiences sadness and anxiety, not everyone will develop an affective or an anxiety disorder during their lives (Kessler et al., 2005). Similarly, all antisocial adults have life-long histories of antisocial behavior but not all adolescents who have conduct problems grow into antisocial adults; most do not (Moffitt, 1993). Indeed, more than half of children report that they experience psychotic-like experiences but only a small proportion of adults will develop a psychotic-like disorder (Laurens et al., 2007; Morgan et al., 2011). As well as there being groups of people who do and do not develop threshold mental disorder(s) during their lives, people who do experience threshold mental disorders tend to oscillate between experiencing subthreshold symptoms and their threshold disorder (e.g., Bienvenu et al., 1998). These data suggest that people experience mental illness to varying degrees and vary in their propensity to develop active mental illness.

Structural research supports the conclusion that people experience mental health problems to different degrees. Item response modeling is a latent variable technique that has provided unique insights into the dimensionality of specific mental disorders as well as the relationship between the symptoms that are used to define the disorder and the severity of the disorder. Item response modeling achieves this by describing the relationship between the probability of reporting psychiatric symptoms, diagnostic severity, and the psychometric characteristics of symptoms (Reckase, 2009). Specifically, this probabilistic relationship is described using a 'person parameter' (e.g., theta) that indexes the severity of the respective person being asked about their psychiatric experiences. In addition to the person parameter, 'item parameters' are used to describe the relationship between diagnostic latent severity, symptom characteristics, and the probability of endorsing the symptom. These are a *discrimination parameter* (i.e., an *a*-parameter) that reflects the ability of the symptom to distinguish between continuous degrees of the underlying disorder factor and a *difficulty parameter* (i.e., *b*-parameter) that describes the degree of severity that equates to a 50% likelihood of endorsing the symptom. (Note that the number of *b*-parameters used in item response modeling is equal to the number of categories used to measure the presence of the symptom minus one. The meaning of the difficulties parameters will vary as a function of the number of response

categories.) A key example of how item-response modeling has been used to refine clinical phenotypes comes from the substance-use literature. In DSM-IV, substance-related disorders were classified using separate abuse and dependence categories. The validity of continuing to delineate between substance abuse and dependence in DSM-5 was tenuous. Contrary to the biaxial DSM-IV classification, replicated data from clinical and epidemiologic samples showed that substance abuse and dependence reflected one latent construct. Item-response modeling studies that examined how the DSM-IV abuse and dependence criteria indexed the latent construct of substance misuse also showed that the abuse criteria did not always index milder substance misuse than the dependence criteria (Langenbucher et al., 2004; Lynskey and Agrawal, 2007; Teesson et al., 2002). As a result of these data, the DSM-IV abuse and dependence criteria were coalesced into single diagnostic categories for each respective substance type in DSM-5.

People Experience Mental Disorders in Different Ways

In contrast to the homogeneous assumptions of most randomized controlled trials, epidemiological and clinical data show that people who experience mental disorders do so in heterogeneous ways. This means that two patients who meet the diagnostic criteria for the same disorder can experience the disorder in very different ways. *Latent class analyses* are one of the latent modeling techniques that have provided insights into the different ways that individuals experience mental health problems. Latent class analyses are 'person-centered' analyses that identify discrete groups of people based on the endorsement of observed variables such as psychiatric symptoms (Lazarsfeld and Henry, 1968). Latent class analyses do not make a priori assumptions about the number of different ways that people experience psychiatric symptoms or how specific people experience psychiatric symptoms. Instead, latent class analyses identify the number of groups and the group membership of people based on how and which symptoms they report (Lazarsfeld and Henry, 1968). Researchers have used latent class analyses to examine, for instance, the different ways that individuals experience depression. These studies have shown that individuals can experience 'severe depression' and tend to experience all of the DSM-IV depressive symptoms. Individuals can also experience 'psychosomatic depression' (e.g., changes in appetite, sleep disturbances, psychosomatic complaints, and impaired concentration) or 'cognitive-emotional' depression, which is characterized by feelings of worthlessness and excessive guilt, difficulty concentrating, and suicidal thoughts (Carragher et al., 2009; Sullivan et al., 1998). Indeed, there are clinically meaningful subtypes of other mental disorders such as panic disorder (Goodwin et al., 2002; Kircanski et al., 2009; Roberson-Nay and Kendler, 2011) and social phobia (Kessler et al., 1998).

Improving the 'Evidence' in Evidence-Based Psychiatry

Although multiple disorders share risk factors and clinical correlates and people experience specific mental disorders to varying degrees and in different ways, evidence-based psychiatry should not be disbanded by mental health professionals or the governments that fund health services. Instead, there are quantitative methods that are available that could be employed in randomized controlled trials in ways that would account for the nature of mental disorders. These methods, if employed in randomized controlled trials, would mitigate the criticism of evidence-based psychiatry that psychiatric disorders have limited validity and by association so do randomized controlled trials that use disorders as their primary outcome measure.

Generalized mixture models provide one way of improving the 'evidence' in evidence-based medicine. Generalized mixture models can be used to examine the trajectories of change of single or multiple observable variables such as psychiatric symptoms and can map the trajectories of continuous and categorical observable variables (Muthén et al., 2002). This means that generalized mixture models avoid the homogeneous designs that are typically employed in randomized controlled trials and can be used to examine how patients' presenting symptoms influence their treatment response by providing:

- a way to identify groups of patients whose symptom profiles differ and
- a way to examine whether these discrete groups differ in their trajectory and/or rate of treatment response.

For example, generalized mixture models could account for the nature of mental disorders by examining how the comorbid symptoms of multiple disorders influence treatment response and thereby account for the fungible boundaries between categorical diagnoses. Moreover, generalized mixture models could be used to examine how individual differences in psychiatric experiences influence treatment response. Randomized controlled trials that employ generalized mixture models would therefore avoid the homogeneous assumptions that have been argued to be a limitation of evidence-based psychiatry.

A limited number of randomized controlled trials have used generalized mixture modeling to examine the relationship between clinical characteristics and treatment response. For example, generalized mixture models of depression have shown that some depressed patients improve with treatment, some patients get more depressed with treatment, and for some patients treatment has no effect (Cuijpers et al., 2005; Gunn et al., 2013; Sunderland et al., 2012). Patients with different degrees of depression also experience change at different times during treatment (Lutz et al., 2009) and respond to different treatments, for instance, combination therapy is more effective than monotherapies for some depressed patients (Stulz et al., 2010). Depressed patients who respond differently to treatment also differ in terms of their sociodemographics and clinical correlates including age of onset, comorbidity, and familiality of psychopathology (Cuijpers et al., 2005; Gunn et al., 2013). There has been sparse use of generalized mixture models in anxiety and substance-use trials. Although generalized mixture models are only now making traction in the clinical treatment literature, the aforementioned studies demonstrate that the limited validity of categorical psychiatric disorders does not need to be a limitation of evidence-based psychiatry.

Conclusions

The process of evidence-based psychiatry can benefit patients, mental health practitioners, and the governments that fund mental health services by promoting the use of efficacious, effective and/or efficient treatments. Like any method, evidenced-based psychiatry has its limitations. Randomized controlled trials fall at the apex of the evidence hierarchy. Yet despite the limited validity of categorical psychiatric disorders, randomized controlled trials use these disorders as their primary outcome variable. This practice does not reflect the nature of mental disorders accurately. Pragmatic approaches such as item response, latent class, and generalized mixture modeling are gaining traction in the epidemiological and clinical literature. These methods can be used both to identify epidemiologically meaningful input variables for randomized clinical trials as well as identifying how individual differences in mental health problems influence trajectories of clinical change. Incorporating these latent variable methods in future randomized controlled trials would improve the 'evidence' in evidence-based psychiatry by accounting for the nature of mental illness.

Evidence-Based Psychotherapy

Abstract

This article presents the conceptual and methodological foundations of evidence-based psychotherapies (EBPs). Starting with a definition and guidelines for EBP, it gives a short overview of the historical development of psychotherapy research and EBP. It describes different types of psychotherapy research, such as efficacy, effectiveness, efficiency, and process research, and discusses several methodological issues concerning research design, selection of samples, and outcome criteria, as well as the interpretation of research results. The article closes with a short overview of EBP within the field of treatment of depression and anxiety.

Introduction: What Is Evidence-Based Psychotherapy?

The term evidence-based psychotherapy (EBP) refers to empirically tested psychotherapeutic treatments and strategies. Hence, EBP requires above all empirical data and knowledge on *outcomes* based on informative and meaningful studies of clinically representative samples. However, recent psychotherapy research also includes more complex studies such as analyses of treatment aptitude (e.g., which treatment is most effective for whom and under what circumstances), specifications of processes of change (how and why clients improve and what are the most important predictors of positive outcomes), and calculations of the efficiency of psychotherapy (cost–benefit ratios).

In recent years, the movement toward EBP can be traced back to the initiatives of a Task Force set up by the Clinical Section of the American Psychological Association (see Chambless and Hollon, 1998) that developed specific guidelines for identifying empirically supported therapies (EST). According to these guidelines, a therapy can be assumed to be empirically based if it meets a set of methodological and substantial criteria. For example, well-established treatments require (1) at least two between-group design studies (i.e., at least one treatment and one control group that are compared before and after the intervention) conducted by two independent research groups; (2) studies using a treatment manual, specified clinical groups, and reliable and valid outcome criteria; and (3) results that demonstrate superiority to medication, placebo control, or alternative treatments *or* equivalence to already established treatment. As an alternative to experimental between-group studies, these results can also be gained from a larger series of single-case experimental designs (the Task Force group suggested a minimum of 9).

Evidence in support of psychotherapy has increased dramatically over the last 30 years (Lambert and Ogles, 2004). However, as to be expected, the entire 'shift' toward EBP and EST guidelines has been very controversial with concerns ranging from what is the best way to collect and analyze 'the evidence' (see the section Selected Methodological and Conceptual Issues) to the necessary criteria for attaining an evidence-based status. This has led to alternative and extended guidelines and lists of EBP (Chambless and Ollendick, 2001). These lists have subsequently been updated and revised to cover new aspects such as evidence-based therapist–patient relationship factors (e.g., Norcross, 2002).

A Short History of EBP and Psychotherapy Research

The movement toward EBP started with a programmatic article published by Hans-Jürgen Eysenck in 1952 stating that the empirical studies on psychotherapy available at that time indicated that the effectiveness of psychotherapy was not superior to spontaneous remission. This general criticism led to a widespread promotion of psychotherapy research over the following decades. The hundreds of controlled studies that followed resulted in an extensive body of outcome research. Initial systematic reviews, especially the first meta-analysis by Smith and Glass (1977), Smith et al., 1980 have largely confirmed the general effectiveness of psychotherapeutic treatments. However, even in these first systematic reviews, the authors already discussed a more differentiated view because, for example, not all approaches and methods seemed having had the same degree of empirical support.

As a result, the question that therapeutic approach works best is still being evaluated and discussed intensively up to today (Wampold, 2013). However, the stage marked by the competition between rival therapeutic approaches has been supplemented by treatment aptitude research focusing on which treatment is most appropriate for which kind of problem. In addition, it has been argued that it is more important to understand the changes during the therapeutic process and which main factors within this change lead to successful psychotherapies (Orlinski et al., 2004).

Today, hundreds of systematic reviews and meta-analyses summarizing results on different approaches (e.g., cognitive behavior therapy), on different mental health problems (e.g., depression), and on different therapeutic factors (e.g., therapist–client relationship) are available (see Lambert and Ogles, 2004; Orlinski et al., 2004). The most recent developments in psychotherapy research, however, are attempts to identify more general factors or therapeutic principles instead of validating specific therapy procedures or methods. Nonetheless, despite this movement toward a general psychotherapy, there is still an extensive discussion on the relative effectiveness of different

 http://dx.doi.org/10.1016/B978-0-08-097086-8.21081-7

therapeutic approaches. To some extent, these discussions may arise from the different professional identities that are still common in psychotherapy research and practice (e.g., researchers/therapists with psychodynamic vs behavioral orientations). These identities lead to different interests and may blur the perception, analysis, and interpretation of empirical results (Gaudiano and Miller, 2013).

Types of Psychotherapy Research

Consumer Satisfaction

Consumer satisfaction studies come from the tradition in market research by asking clients how satisfied they are with a product or service. These are mostly based on surveys using large representative samples. This perspective on psychotherapy was long ignored, probably because client satisfaction with therapy was viewed as a less valid criterion. However, this perspective on outcome research has also confirmed the general efficacy of psychotherapy. One prominent example is Seligman's (1995) study that provided additional evidence that participants of psychotherapy benefit from a broad array of treatments. At the same time, one should be aware of important methodological limitations to this approach such as the use of posttherapy retrospective ratings as a measure of improvement as well as biased selection within samples.

Efficacy/Effectiveness Research

The most important question for EBP concerns the outcomes of psychotherapeutic treatments. Outcome research can be differentiated into *efficacy research* (i.e., outcome research under well-controlled settings with randomized trials) and *effectiveness research* (i.e., outcome research in clinically representative settings). The most important issues in these types of research are the study design, the threats to internal and external validity, and the selection of outcome criteria (see the section Selected Methodological and Conceptual Issues). Randomized controlled trials (RCTs) are regarded as the 'gold standard' of efficacy research, whereas quasi-experiments are typically used in effectiveness research. There are several differences between these two strategies, for example, homogeneous versus heterogeneous clinical samples or randomization versus statistical control as strategies for controlling between group differences. However, although RCT and efficacy research is viewed as a necessary strategy for EBP, effectiveness research is viewed as a complementary step for the transfer of EBP into evidence-based practice.

Efficiency Research

Because financial costs and resources have become an important issue in health care systems, the question of costs in relation to benefit are also important in psychotherapy and EBP. Efficiency research can be divided into cost–benefit and cost-effectiveness analyses (Yates, 1995). Cost–benefit analyses compare the monetary cost of psychotherapy in relation to its monetary benefits. Monetary costs are usually taken to be the cost of the therapy itself, the loss of working time for the client, the cost for qualification and training of therapists, materials expenses such as rental costs for rooms, and so forth. Monetary benefits are, for example, lower cost for medical treatments, fewer days out of work, more taxes paid, and the like. However, because effects of psychotherapy are usually hard to calculate in monetary terms (e.g., what is the monetary benefit of a better marital relationship?), cost-effectiveness analyses are replacing monetary value as a way of measuring the benefits of a particular outcome (e.g., how much money is necessary to cure someone from depression with a particular treatment?). Although the efficiency of psychotherapy has been evaluated much less than its efficacy, existing results usually reveal that psychotherapy is also successful in monetary terms (see, e.g., Layard et al., 2007).

Process Research

Psychotherapy process research aims to specify relevant change processes during treatment and identify those within-treatment factors that allow the best prediction of successful outcomes. In general, the specification of relevant change processes should lead to a better fit between psychotherapeutic treatments and client characteristics (treatment aptitude studies) and a better understanding of general factors and mechanisms of change (Orlinski et al., 2004). Psychotherapy process research is diverse and covers various issues and levels of analysis. For example, process characteristics can range from microlevel variables such as concrete therapist–client interaction to characteristics of therapeutic sessions and specific phases (e.g., how well a sustainable therapeutic bond between therapist and client has been established) up to the analysis of biographical change processes over years. In addition, process research can be conducted in several ways, for example, by identifying characteristic patterns of change during therapy, outcomes moderators (e.g., results for specific subgroups), and outcome mediators (e.g., quality of therapist–client relationship in relation to outcomes). In general, a number of process characteristics have been identified as having a significant effect on psychotherapy outcomes. For example, a number of studies have found that variables such as a positive therapeutic bond or alliance are the most influential characteristics of a successful psychotherapy (Orlinski et al., 2004).

Meta-Analysis

Because thousands of efficacy and effectiveness studies have investigated outcomes of psychotherapy over the past decades, systematic efforts have been made to summarize these results via meta-analysis. The term meta-analysis refers to systematic methods for aggregating empirical results of different primary studies on the same topic, and it is a widely used approach in psychotherapy research (Lambert and Ogles, 2004; Lipsey and Wilson, 1993). Typically, a meta-analysis starts with an exact definition of the eligibility criteria for the inclusion of a study in a research review (e.g., what kind of intervention has been evaluated, which clients have been treated, etc.) followed by an intensive literature search based on these selection criteria. After systematically coding the characteristics of the included studies, unified effect size parameters are calculated for each

study. This metric allows the calculation of mean results across a large body of studies and the identification of which study characteristics systematically relate to the results.

At the beginning of the meta-analytic era, this approach was used for broadband reviews of psychotherapy outcomes. For example, Smith and Glass (1977) found a mean effect size of $d = 0.85$ across 475 studies, indicating that the average psychotherapy client is superior to 80% of the controls receiving no or only placebo treatment. More recent psychotherapy meta-analyses have addressed specific questions, such as specific treatments, specific disorders, specific therapist factors, or even combinations of these factors (e.g., Butler et al., 2006; Cabral and Smith, 2011; Cuijpers et al., 2011; Tefikow et al., 2013). Meta-analysis has also been used to integrate comparative treatment research in which different therapeutic approaches are compared directly (e.g., Shapiro and Shapiro, 1982; Tolin, 2010). In sum, meta-analytic research has revealed that psychotherapy is generally effective over a great variety of mental health disorders; that cognitive behavioral therapy is the best investigated approach; and, finally, that although a lot of within-therapy factors influence psychotherapy outcomes, the therapeutic alliance between therapist and client is the fundamental base for therapeutic change.

Research on Transfer into Evidence-Based Practice

In addition to gathering evidence on the empirical foundation of psychotherapy, the evidence-based movement and the development of treatment guidelines aim to promote evidence-based practice. However, recent research has shown that – as in other fields of intervention – transferring EBP into practice is not an easy task. As a result, a macroperspective on the dissemination of EBP within the health services and the road to evidence-based practice is becoming an important field of research (see Gaudiano and Miller, 2013). This entails implementation control and at least a basic documentation of the implementation of individual therapies (e.g., within systematic quality assurance), as well as research on the disseminability, availability, acceptability, and utilization of EBP within the mental health services.

Selected Methodological and Conceptual Issues

Research Designs

Research designs are strategic plans for examining causal effects, that is, plans regarding how to confirm proposed effects of psychotherapy in a valid way. RCTs are viewed as the 'gold standard' in EBP. Within RCTs, clients are assigned randomly to experimental groups in studies typically comparing one or more treatment condition with one (or more) control condition. Relevant outcome criteria are then used to assess these groups at least before and after the treatment.

There are different types of nontreated controls such as placebo, attention, low-intensity, or no-treatment conditions. Placebo or attention controls are applied to control unspecific effects of psychotherapy (i.e., effects due simply to applying some kind of treatment). However, the rationale of placebo and attention groups is discussed in a controversial manner, because it is argued that these 'unspecific' effects are a genuine part of psychotherapeutic treatments. Real no-treatment conditions are often questioned for ethical reasons (i.e., no treatment in the case of psychological disorders). Therefore, studies often apply waiting list controls (i.e., clients who will receive therapy after the posttest assessment). Apart from the discussion on control conditions, the assessment of long-term effects (e.g., follow-up assessments after the termination of treatment) is regarded as crucial for EBP.

Because randomization is not always possible, at least in clinical settings, design alternatives such as quasi-experiments and single case studies are frequently used to evaluate psychotherapeutic treatments. Within quasi-experiments, assignment to groups (treatment vs controls) is not based on randomization. In fact, effectiveness studies within real clinical settings often try to collect data on widely comparable units (clients from Clinic A vs Clinic B) when examining the outcomes of psychotherapy. Of course, these strategies have disadvantages due mainly to limited comparability and subsequent threats to validity such as selection bias (see below). However, it is argued that they have a higher external validity and are more appropriate for generalization and the transfer to practical settings. Nonetheless, depending on the special field of investigation, these designs really suffer from having limited value in claiming causal inference.

Another problem in psychotherapy research is collecting sufficiently large and homogeneous clinical samples, because some disorders are relatively rare. One solution in these cases is experimental single-case designs (see Kazdin, 2011). These study individual cases more intensively and under special conditions in order to make valid causal inferences. One of the most frequently used single-case designs is the multiple baseline design (MBD). MBD uses continuous assessments prior to (baseline), within, and after psychotherapeutic treatments. The design varies according to whether there are multiple cases (more than one), multiple behaviors (treatment effects are tested on at least two different behaviors), or multiple settings (treatments in different situational conditions). The core principle of this design is that these multiple units are not tested at the same time but successively in order to see whether a possible effect appears repeatedly. This repeated testing should strengthen the causal inference.

Problems in Recruitment and Selection into the Treatment

One of the most challenging tasks within empirical clinical studies is to collect comparable treatment and control groups that are matched in terms of sociodemographic variables, type and severity of clinical disorder, motivation for therapy, and so forth. Randomization prior to therapy with RCTs should guarantee that clients are initially comparable. However, premature termination of treatment and attrition in experimental studies are still possible even in RCTs, and these aspects need to be considered when analyzing the results. For example, highly motivated clients usually have a higher probability of being assigned to the treatment conditions because they will terminate their participation in a study if randomly assigned to the control group (or, vice versa, less motivated clients will terminate treatment prematurely). These selections

into treatment can cause severe threats to validity, because motivation for change at the beginning of the treatment normally correlates significantly with the treatment outcome, and this usually leads to an overestimation of treatment effects. Quasi-experiments (in which complete comparability is not expected) offer some strategies for controlling or enhancing comparability (also used in RCTs when randomization failed). For example, one can search for comparable units on the individual level (i.e., two individuals share a set of same characteristics and then one of these experimental 'twins' is assigned to the condition at random). With respect to premature termination and attrition, researchers should at least control whether terminators differ from completers on relevant characteristics (e.g., sociodemographic variables, pretest level of outcome criteria). A more specific technique is intention-to-treat analysis (ITT). This compares all clients in the treatment group (regardless of whether they terminate treatment) with subjects in the control condition. Using this strategy, premature termination usually leads to lower estimations of treatment effects because terminators are expected to have weaker outcomes then completers. However, ITT works on the premise that terminators do not leave the entire study (at least pre–posttest data should be available). Finally, comparability can also be achieved by statistical procedures. One of the simplest strategies is analysis of covariance in which treatment outcomes are corrected for significant covariates (e.g., initial values of the outcome criteria). Modern statistical procedures use techniques such as propensity score matching to attain comparability among comparison groups. Estimated propensity scores are used to select comparable clients for the treatment and control condition or correct results according to these propensity scores. The propensity scores are usually calculated on the basis of empirically derived predictors that lead to selection into treatment and as a result, they control associated threats to validity (e.g., selection bias).

Type of Outcome Criteria

Selecting reliable and valid outcome criteria is an important step in a psychotherapy study. This includes not only methodological (e.g., psychometric quality of assessment tools) but also substantial (e.g., what will be measured?) issues. Substantial issues relate to the goals of treatment and imply the operationalization of outcome criteria derived from these goals. In general, psychotherapy has three global aims: (1) to cure from a disorder or at least relieve symptoms or problems; (2) to promote client development (e.g., personality change, adaptive functioning); and (3) to promote the client's general quality of life. Curing a disorder or relief from symptoms is superordinate to both others goals, because a decrease in problems will naturally lead to an increase in a person's development and quality of life. Specifying outcome criteria to measure these goals basically has to address the following four questions:

- What should be assessed?
  The first step is to determine the *content of outcome criteria*. For example, what should be assessed when treating depression? In general, three types of measures are applied: (1) ratings of client satisfaction with the treatment and subjective ratings of the outcome; (2) clinical measures assessing the symptoms, disorders, and important individual problems; and (3) additional assessments of important psychosocial aspects and further outcomes. Satisfaction with the treatment and direct subjective ratings of effects are usually applied within consumer satisfaction studies (see above). Clinical measures include the assessment of the clinical status through clinical interviews using approved clinical diagnostic systems (ICD-10, DSM-V), an assessment of clinical symptoms by symptom list (e.g., the Symptom Checklist-90-R), and problem-related assessment tools (e.g., rating tools such as the Beck Depression Inventory). In addition, it is considered useful to evaluate psychotherapy by individualizing treatment goals according to each individual client and assessing the expected and real changes using, for example, goal attainment scaling (GAS). GAS is an assessment tool that reviews defined individual treatment goals by using a uniform rating of expected versus real improvements. Finally, most psychotherapy studies apply additional aspects of the outcome measurement, such as self-control, self-efficacy, quality of life, and personality assessments. Independent from this selection, outcome criteria should also consider different types of human cognitions, emotions, and behavior (i.e., multitrait assessment).
- What kind of assessment tool?
  The selection of the assessment method depends upon the psychometric properties (e.g., standardization, reliability, validity) of the method as well as on its practicability and past utilization. It is advisable to use at least two different methods (i.e., multimethod assessment), although the cost of collecting data and the availability of informants have to be taken into account (e.g., collecting observational data is normally time consuming). Especially in psychotherapy treatment research, instruments should be standardized for clinical populations. However, the application of standardized tests is not without its problems, because these have usually been constructed to assess status and not change. Therefore, it is necessary to select instruments with a demonstrated sensitivity to psychological and clinical change.
- Who is the informant?
  To some extent, the effects of psychotherapy also depend on the informant, that is, on who delivers the data on possible changes. There are several options here: the client, the therapist, independent experts, or relevant others (e.g., partner, parents in case of child psychotherapy). The most important informant is the client, although multi-informant assessment is usually preferable.
- When to collect the data?
  Outcome criteria can be assessed in three different ways: one single measurement after the termination of the therapy (direct change measurement); pre–postcomparisons, preferably with long-term follow-ups; and, finally, multiple measurements at baseline, within, and after therapy. Multiple measurements are naturally expensive, but deliver detailed and reliable information on therapeutic processes. In addition, repeated follow-ups are considered to be necessary for evaluating long-term effects.

Statistical Analysis and Interpretation of Results

The statistical analysis of outcomes depends mainly on the time and frequency of assessment points. In general, there are three different statistical indicators for therapeutic improvements: First, improvement rates can be calculated based mainly on clinical diagnoses of clients (e.g., proportions of improved clients compared to nontreated groups). Second, pre–posttest data are usually confirmed by *statistical* and additionally by *clinical significance* (Ogles et al., 2001). Clinical significance requires comparisons between a treated clinical group and normative scores (e.g., from nonclinical groups). Clinical significance is assumed when treated clinical groups score as high as members of a nonclinical group. Finally, change can be expressed as standardized *effect sizes* as applied mostly within meta-analyses (Ellis, 2010). Most common in intervention research is the *d* index (standardized differences between a treated and a nontreated group at posttest or follow-up expressed in standard deviation units) and the odds ratio (odds for improvement within the treated vs nontreated group).

Conflict of Interest

One important aspect of psychotherapy research concerns the independence of results. Meta-analytic data have revealed that psychotherapy studies carried out by program developers or proponents of a specific treatment approach deliver higher effects than studies that are not influenced by some kind of personal or financial conflict of interest. These influences emerge when, for example, program developers are not willing to publish negative or zero results on 'their' treatment (the so-called publication bias) or report only significant results in their publications. To counter such sources of bias, the aforementioned treatment guidelines insist on at least one independent replication study with comparable results before an EBP can be assumed.

Evolution of EBP

Different types of research have indicated that the evolution of EBP cannot be achieved by one single study. Therefore, the development of EBP is normally a process passing through

Table 1 Empirically supported psychotherapeutic interventions for anxiety and depression

Disorder	*Treatment*	*Empirical support*	*Conclusion*
Depression	Behavior therapy	Strong	Efficacious
	Cognitive therapy	Strong	Efficacious
	Cognitive behavioral analysis system of psychotherapy	Strong	Efficacious
	Interpersonal therapy	Strong	Efficacious
	Nondirective supportive therapy	Strong	Efficacious
	Acceptance and commitment therapy	Modest	Probably efficacious
	Behavioral couple therapy	Modest	Probably efficacious
	Emotion-focused therapy	Modest	Probably efficacious
	Short-term psychodynamic therapy	Modest	Probably efficacious
Generalized anxiety disorder	Cognitive and behavioral therapies	Strong	Efficacious
Obsessive-compulsive disorder	Behavior therapy (exposure and response prevention, ERP)	Strong	Efficacious
	Cognitive therapy	Strong	*Without ERP only probably efficacious*
	Acceptance and commitment therapy	Modest	Probably efficacious
	Eye movement desensitization and reprocessing	Modest	Probably efficacious
	Stress management	Little	Likely not efficacious
	Psychodynamic therapy	Little	Likely not efficacious
Panic disorder	Cognitive behavior therapy	Strong	Efficacious
	Applied relaxation	Modest	Probably efficacious
	Psychodynamic treatment	Modest	Probably efficacious
Post-traumatic stress disorder	Prolonged exposure	Strong	Efficacious
	Present-centered therapy	Strong	Efficacious
	Cognitive processing therapy	Strong	Efficacious
	Stress inoculation therapy	Modest	Probably efficacious
	Eye movement desensitization and reprocessing	Strong	Efficacious
	Psychological debriefing	Little	Likely not efficacious Potentially harmful
Social phobia	Cognitive and behavioral therapies	Strong	Efficacious
Specific phobias	Exposure therapies	Strong	Efficacious

Based upon the American Psychological Association, 2008; modified by updated results from several recent meta-analysis articles (e.g., Cuijpers, P., Andersson, G., Donker, T., van Straten, A., 2011. Psychological treatment of depression: results of a series of meta-analyses. Nordic Journal of Psychiatry 65, 354–364; Hollon, S.D., Ponniah, K., 2010. A review of empirically supported psychological therapies for mood disorders in adults. Depression and Anxiety 27, 891–932).

successive steps. At the beginning, pilot studies with group samples or a single-case design is used to test the general acceptability and feasibility of a novel psychotherapeutic method. Subsequently, RCTs – ideally from different research groups – are needed to confirm the efficacy of this new approach. These studies should be followed by preferably diverse effectiveness studies to test the application in practice. These studies should be supplemented by efficiency and process-outcome studies to determine cost–benefit ratios and provide information on relevant therapeutic processes. Finally, studies on dissemination should be conducted to investigate the transfer to mental health services and evidence-based practice.

Evidence-Based Psychotherapies

After about 60 years of intensive research on psychotherapy outcomes, there is now an extensive body of research showing that EBP can help patients to maintain mental health and increase their quality of life (APA, 2013). However, as the body of evidence for psychotherapy approaches is so vast, a complete illustration of EBP would go beyond the scope of this article (see Chambless and Ollendick, 2001; Chambless and Klonsky, 2013; or relevant web sites, e.g., http://www.psychologicaltreatments.org and http://www.evidencebasedpsychotherapies.org, for reviews). As an example, **Table 1** presents an overview of EBP in the field of depression and anxiety as two very prevalent mental disorders.

The most promising approach across all types of depression and anxiety disorders is cognitive and behavior therapies (CBTs). CBT encompasses various approaches and has a large body of evidence that it successfully treats these disorders. A recent meta-analysis of nonrandomized effectiveness studies on outpatient CBT for anxiety disorders (Hans and Hiller, 2013) has also demonstrated that outpatient individual and group CBT is very effective in routine practice settings and has a high level of acceptability among clients. Other therapeutic approaches and methods have more specific potentials. Examples are interpersonal psychotherapy on depression or eye moment desensitization and reprocessing on post-traumatic stress disorder.

Conclusion

Taken together, there is substantial evidence that psychotherapy is efficacious. This is true for a number of different approaches, although not all demonstrate similarly strong evidence across all disorders. However, when focusing on the relative efficacy of these treatment approaches, recent reviews have shown that it is difficult to confirm superiority of any one approach over another. When only studies directly comparing two treatments are considered (which were both intended to be used in therapeutic settings, i.e., bona fide psychotherapies), many yield effect sizes around zero (e.g., Benish et al., 2008; Wampold et al., 2011). This implies a lack of superiority of one evidence-based treatment (classified either as strong or modest in comparison to a control group; see **Table 1**) over another (Benish et al., 2008) and also illustrates that the relative efficacy of evidence-based therapies (EBTs) versus treatment-as-usual (TAU) may depend on the specific TAU conditions (Wampold et al., 2011). For example, EBT is relatively more effective when TAU is defined as minimal mental health services. However, it does seem less efficacious when compared to psychotherapy services delivered in routine care. Another example is a recent meta-analysis comparing the efficacy of seven psychotherapeutic interventions for patients with depression (Barth et al., 2013). Again, each of the psychotherapeutic interventions was deemed superior to a waiting list control condition (with moderate-to-large effect sizes), whereas comparisons between these interventions yielded at best small effect sizes.

These results have encouraged researchers to focus on general principles of change rather than on comparisons between therapy procedures or methods. For example, Goldfried (2013) has recently suggested five common change principles on the basis of empirical evidence: (1) facilitating expectations that therapy can be helpful; (2) establishing an optimal therapeutic alliance; (3) facilitating the patient's awareness of those factors within themselves, others, and their environment that contribute to their problems; (4) facilitating corrective experiences; and, finally, (5) encouraging continued reality testing. These principles are supposed to reflect general change processes across different treatment procedures. Indeed, deriving principles of change from the large body of evidence available for psychotherapies maybe more helpful in developing evidence-based practice than comparing outcomes for different treatment procedures.

Evidentials in Linguistics

Zlatka Guentchéva, LACITO – CNRS (Centre National de la Recherche Scientifique), Paris, France

© 2015 Elsevier Ltd. All rights reserved.

This article is a revision of the previous edition article by Z. Guentchéva, volume 7, pp. 4972–4975, © 2001, Elsevier Ltd.

Abstract

This article presents an overview of the notions of evidentials and evidentiality. It briefly outlines the history of evidentials and the various types of evidentiality established. It looks at these notions' semantics and summarizes some of the more influential publications on the matter. It further looks at interaction between evidentials and tense/aspects morphemes, and discusses some theoretical issues. It mentions some sources for the emergence of evidentials and recent controversy over grammatical versus lexical approaches.

The label evidential originated in descriptions of verbal affixes in American Indian languages where evidence for certain statements must be specified (e.g., dreams, sounds, hearsay, inferences, sightings, cf Boas, 1911, 1947). It occurs once in Boas' posthumously published *Kwakiutl grammar* (1947, p. 237) but the notion is retained in several of his studies on verbal categories, and is generally discussed under the heading 'source of information' with the gloss 'evidently (as is shown by evidence)' (Boas, 1947, p. 245; 1911, p. 496; see Jacobsen (1986, p. 4–7) and Aikhenvald (2004, pp. 11–17) for further references of grammaticalized information sources). However, it was Jakobson (1957/1971, p. 135) who first introduced the term in a broad theory of generic verbal categories as "a tentative label for the verbal category" seen as an interaction between three events: "a narrated event (E^n), a speech event (E^s), and a narrated speech event (E^{ns}), namely the alleged source of information about the narrated event. The speaker reports an event on the basis of someone else's report (quotative, i.e. hearsay evidence), of a dream (revelative evidence), of a guess (presumptive evidence), or of his own previous experience (memory evidence)." This is illustrated by Bulgarian examples contrasting with 'direct narration' ($E^{ns} = E^s$) versus 'indirect narration' ($E^{ns} \neq E^s$): *zaminala* 'it [the steamer] is claimed to have sailed' versus *zamina* 'I bear witness; it [the steamer] sailed.'

Referring to grammaticalized information sources, evidentials were first related to a closed class set of obligatory verbal morphemes denoting the source of subjective knowledge or the source of information (for an historical overview see Jacobsen, 1986; de Haan, 1999, 2001; Comrie, 2000; Aikhenvald, 2004; Plungian, 2010). The notion appears to have become well-established by the mid-1960s (Jacobsen, 1986: 6) but it seems to have been used rather infrequently by Americanists until the publication of the collective volume by Chafe and Nichols (1986). It was progressively extended to a repertoire of grammatical devices coding the different kinds of information sources on which statements are based, and used in descriptions of typologically different languages. In this 'broad sense,' evidential markers encode not only the type of information source but also the speaker's attitude toward the reliability of the information (based on hearsay or inference), as well as the degree of probability underlying the truth value of the utterance (Chafe and Nichols, 1986, p. vii, Mithun, 1986) or its epistemological assessment independently of its grammatical status (Chafe, 1986). As a result, the relations and boundaries between epistemic modality and evidentiality has been often debated: evidentiality has been categorized as part of modality or speaker beliefs (Palmer, 1986); from a typological point of view, Van der Auwera and Plungian (1998, pp. 85–86) show various forms where the two notions cluster, more precisely in the inferential domain; the diachronic relationship between the two notions has been questioned by Bybee et al. (1994, pp. 195–205); de Haan (2005) has noted that there is a connection between evidentiality and deixis. Data from different languages show that evidentiality does not relate to the truth or falsity the speaker's statement (Guentchéva, 1996, p. 11; Lazard: 2000, p. 212; Aikhenvald, 2003, 2004, p. 5, Joseph, 2003, p. 309).

The notion of evidentiality became mainstream mostly in linguistics after the publication of the collective volume by Chafe and Nichols (1986), as well as papers published by Barnes (1984) and Malone (1988) on Tuyuca, or Willett's first typological study (1988), and especially with Aikhenvald's monograph (2004) dealing exclusively with the category of evidentiality in a cross-linguistic perspective. Numerous articles dealing with various meanings of evidentials, and other collective volumes have been published such as Guentchéva (1996), Johanson and Utas (2000), Aikhenvald and Dixon (2003), Guentchéva and Landaburu (2007), and Diewald and Smirnova (2010), as well as the special issues of the *Journal of Pragmatics* 33 (Dendale and Tasmowski (eds), 2001) and of *Functions of Language* 16 (1) (2009).

In formal linguistics, Cinque (1999) was the first to include evidentiality as a separate category distinct from modality in his work on the cartography of the syntax structure. In formal semantics, several studies on evidentials in Cuzco Quechua have been carried out, for example, Faller (2002). Interaction between evidentiality and culture has also been investigated in anthropological linguistics (Basso, 2008).

Earlier descriptions of what today would be called evidential systems go back to al-Kāšǧārī's analysis of the

di-past/*miş*-past opposition in *Dīwān Luǧāt at-Turk* (Compendium of the Turkic Dialects) in the eleventh century (Friedman, 1986) and other European studies at the end of the nineteenth century and in the beginning of the twentieth century Haarmann's study (1970) of languages in the Euro-Asian area where 'indirect experience' is analyzed as a separate category and contrasted with neutral verbal forms, rather than as a subtype of a general category expressing information sources, as well other European studies seem to have had little influence on Anglo-American linguistics.

Linguistic terminology is not homogeneous and various terms have been adopted in different grammatical traditions: *indirect* (Haarmann, 1970) or *indirective* for Turkic languages (Johanson, 2000), *nonconfirmative* for Balkan Slavic (Friedman, 1986, 1999), *validational* or *verificational* in Quechua (Weber, 1986), *data-source* in the Jaqi languages (Hardman, 1986), *mediative* (Lazard, 1996; Guentchéva, 1996b), *presumptive* in Romanian, *oposredstvenost* distinguishing *renarrative* and *conclusive* in Bulgarian, *kosvennaja zasvidel'stvannost'* ('indirect evidence') or *zaglasnost* (lit. 'behind one's back') in Russian, etc.

Over the last few decades, the study of evidentiality has given rise to increasingly abundant research. Even though most scholars recognize the notions 'information source,' 'evidence,' 'type of evidence,' 'source of evidence,' or 'mode of knowing' as basic governing principles of the category of evidentiality, it must be observed that these notions are interpreted in different ways and the choice between these notions has clear consequences for analysis of the phenomenon with regard to the diversity of languages. Aikhenvald (2003, pp. 18–20, 2003, pp. 147–151, 2008) and Lazard (2000, p. 214, 2001) advocate a strict grammatical definition of evidentiality and a clear-cut distinction between grammatical and lexical expressions of evidentiality (such as the English adverbs *reportedly*, *allegedly*, and *evidently*, particles referring to verbal report or inference, and parentheticals). On the other hand, scholars such as Squartini (2007), Wiemer (2007), and Boye and Harder (2009) aim to establish functional grounds for cross-linguistic analysis and a unified framework for both lexical and grammatical devices.

It has often been noted that all languages have lexical, syntactic, or other means of referring to information sources, but not all languages have an evidential grammatical category. Grammatical evidentiality "is understood as stating the existence of a source of evidence for some information; that includes stating that there is some evidence, and also specifying what type of evidence there is." (Aikhenvald, 2003, p. 1). Aikhenvald (2004) has brought together data on over 500 languages with obligatory evidential morphemes and reports that about one quarter of the world's languages has some type of grammatical evidentiality. She lists six semantic parameters used in languages with grammatical evidentiality, five being the maximum within a given grammatical system: *visual* (evidence acquired through seeing), *nonvisual sensory* (evidence through hearing, smell, and taste, and sometimes touch), *inference* (based on visible or tangible evidence or results), *assumption* (evidence other than visible results: logical reasoning, assumption, or general knowledge), *reported* (reported information with no reference to who reported it), and *quotative* (information with an overt reference to the quoted source). This can be illustrated with the following example from Tariana, an Arawak language spoken in northwest Amazonia (Aikhenvald, 2004, pp. 2–3):

1. a. Juse irida di-manika-*ka*
   José football 3person.Masc.Sg-play-RECENT.PAST.VISUAL
   'José played football (we saw it)'

   b. Juse irida di-manika-*mahka*
   José football 3person.Masc.Sg-play-RECENT.PAST.NON-VISUAL
   'José played football (we heard it)'

   c. Juse irida di-manika-*nihka*
   Jose' football 3person.Masc.Sg-play-RECENT.PAST.INFERRED
   'José played football (we infer it from visual evidence)'

   d. Juse irida di-manika-*sika*
   José football 3person.Masc.Sg-play-RECENT.PAST.ASSUMED
   'José played football (we infer it from general knowledge)'

   e. Juse irida di-manika-*pidaka*
   football 3person.Masc.Sg-play-RECENT.PAST.REPORTED
   'José played football (we were told)'

Numerous languages, especially within the East Asia-New World complex, encode in their verbal system specific forms for expressing the way in which the information uttered by the speaker has been acquired. However, evidential systems often interact simultaneously with other linguistic categories such as tense and aspect, person, number, and gender. Like Tariana, Tuyuca (Eastern Tucanoan language, spoken in Brazil and Columbia), often presented as having a 'classical evidential system,' distinguishes five evidentials. To say 'he played soccer,' the speaker has to choose the appropriate suffix (Barnes, 1984, p. 256):

2. a. díiga apé-*wi* (I saw him play)

   b. díiga apé-*ti* (I heard the game and him, but I did not see it or him)

   c. díiga apé-*ɣi* (I have seen evidence that he played: his distinctive shoe print)

   d. díiga apé-*ɣigi* (I obtained the information from someone else)

   e. díiga apé -*hĩɣi* (It is reasonable to assume that he did)

As shown in (2), Tuyuca distinguishes: *visual* in (2a), *auditory* in (2b), and *inferential* in (2c), used to present information based on observed traces of an earlier event; *reported* in (2d) and *assumed* in (2e), based on general knowledge about someone's habits. In fact, Tuyuca is a language with very complex interactions between evidentiality and other categories, namely person and tense as illustrated in the following compound construction with an auxiliary verb

where the visual evidential *-wi* interacts with the 'resultative' morpheme *-ri*:

3. Wesé sóe-ri-gɨ nĩi-wi.
   Field burn-RES-Masc.Sg AUX-VIS.3Sg.Masc.PAST
   Gloss: I saw his field and it had been burned
   'He burned his field.' (Barnes, 1984: 259)

It is clear that (3) describes a resultative state due to an earlier event which the speaker did not witness. From a diachronic point of view, the visual suffix could be a relic from an earlier language state (Malone 1988, p. 132); moreover, examples as (3) show that visual interpretation appears to have resulted from the reanalysis of a tense morpheme.

In Wintu, a Pomoan language, evidentiality correlates with aspectual morphemes. According to Schlichter (1986, p. 54), Wintu has an evidential deictic system establishing a strict grammatical distinction between direct 'visual experience' (unmarked) and, indirect experience, that is "an alternative to the temporal orientation of "Western" civilization." It has four evidentials:

4. a. heket wira waca:-bi-**nt^{h}e**ˑ-*m*
   Someone come cry-Imperfective-NON-VISUAL SENSORIAL-DUB=3 person subject
   'Someone is coming crying (I hear)'

   b. Č'epkal neˑ**l** baˑ-bi-**nt^{h}i**-da h
   bad we eat-Imperfective-SENSE-we
   'We have been eating bad things (I sense)'

   c. Minel kir-**ke**ˑ-m
   die asp-hearsay–dub=3 person subject
   'He has died. (I am told)'

   d. Ničay ʔewin suke-**re**ˑ
   Nephew here stand-INFERENTIAL
   'My nephew must have been here (see tracks)'

   e. ʔlmtop nuquˑʔ**el**
   berries ripe-EXPECTATIONAL
   'The berries must be ripe (it is that time of the year)'

The nonvisual *-nt^{h}er* occurs most often in the third person, as in (4a) and involves 'a fact' known to the speaker through a sense other than vision, or by any kind of intellectual experience or 'sixth sense.' It interacts closely with person, agentivity, and aspect. When in first person (where the subject marker *-da* is required) as in (4b), it involves the speaker's experiential role. Suffixes *-keˑ* and *-reˑ* indicate, respectively, information known through hearsay (4c), and information based on inference (4d). Finally, the suffix *-ʔel* in (4e) is usually used to specify the speaker's 'experience with similar situations, regular patterns, or repeated circumstances common in human life.' It thus has an 'experiential' meaning, though it can also function as a hearsay marker in myths. In fact, (4d) and (4e) denote two types of reasoning (Peirce, 1974, vol. II, p. 636; vol. V, p. 171). In (4d), the speaker indicates, with *-reˑ*, that an earlier plausible event can be inferred. The first step of the reasoning process is the presence of the observed traces, that is, 'q'; the second step is the appeal to memorized general knowledge ('if p, then q'); and the third step is that the claim 'p' is plausible i.e., the event has occurred; abduction, made on the basis of the observed traces 'q' and the knowledge of general laws (Desclés, 2000, p. 106). The utterance is therefore a resultative state of the event denoted by 'p.' The use of *-ʔel* is based on generalization: the speaker indicates that his statement is inferred from experience (at this time of the year the berries should already be ripe): 'the existence of phenomena such as we have observed in cases which are similar'; in fact, *-ʔel* encodes inductive reasoning (in the sense of Peirce, 1974, vol. II, p. 636).

In a number of languages, like in Wintu, there are more than one way of marking inference. For instance, Kashaya (Oswald, 1986) has two sets of inferential markers implying two types of reasoning: *-qă*, called the Inferential I (which regularly changes to *-q^h*), and *-bi*, called inferential II (which can co-occur with evidential morphemes):

5. sinam-**q^h**
   drown-INFR.I
   'He must have drowned'

6. duʔk'u-**bí**-na cohtocch-**q^h**
   finish-INFER.II-SS leave-INFER.I
   'He must have finished and left (the work is done and he is no longer here)'

The reanalysis of these two inferentials could show that they are the result of two types of reasoning: *-qă*, used on the basis of the observed traces, implies that the event is reconstructed through abductive reasoning, while *-bi* is not only a distributional variant of *-qă* but also the result of reasoning leading to a probabilistic conclusion.

Evidentiality is also well attested in Tibetan languages where special suffixes indicate that the situation has been seen (*-song*), is common knowledge or has been heard from someone else (*-pare'*), or inferred (*-sha'*) as in the following example (Tournadre, 1996):

7. mātrokungkar-la sāyom-ki' khābgpa Mangpo lo-*'song/ -pare'/-sha'*
   Metrokungkar-LOC earthquake-ERG house many destroy-AUX
   'In Metrokungkar, the earthquake destroyed many houses'

As in other languages, in Tibetan the reportive morpheme *-sa* may co-occur with any of these verb forms, to indicate the source information of the speaker's informant. The system is even more complex, since these markers interact closely with both the person and the semantics of lexical verbs.

Reportive (also referred to as 'reported,' 'hearsay,' and 'renarrative', and also somewhat misleadingly called 'quotative') is one of the more widespread type of markers, and pertains to information obtained through someone else or hearsay, as shown in the following example from Andoke,

an Amazonian language spoken in Colombia (Landaburu, 2007, pp. 36–37):

8. a. ha-ʌtʌ púkə̄ o-ĩ-ti-ʌ b-aya
   your-son canoe this-i.-make-ACCORD3 ENGAG.-i.31
   (Fr. 'C'est ton fils qui fait un canoë')
   'It is your son who is making a canoe'

   b. Ha-ʌtʌ púkə̄ *o-ĩ-ti-ʌ* b-aya-**há**
   your-son canoe this-i.-make-ACCORD3 ENGAG.-i.31-ha
   (Fr. 'C'est ton fils qui fait un canoë, on me l'a dit.'
   '[I am told] it is your son who is making a canoe'

Some languages have more elaborated reportives. In Andoke, for instance, there are different reportive markers depending on discourse functions: for historical facts the speaker uses *-pé*, if he was present and *-hápé*, if the narrated events are old; for myths, a very, experienced shaman uses the suffix *ñé'*, while a shaman who has less authority may also use *-há ñé'* (Landaburu, 2007, p. 40).

In many languages, reportives coexist with indirect speech (which usually involves overt expression of *verba dicendi*, and deictic transposition which 'shifts' person, tense, and mood). In Maricopa (Gordon, 1986, p. 86), there is a special morpho-syntactic device with a complex interaction of aspect, tense, and evidentiality. Cliticized to the invariant verb form *'-ish* or *ish* "say," *-'a* in (10a), it conveys information acquired by hearing in an independent clause, while *-k* in (10b) introduces 'a complement whose verb is not marked with switch reference suffixes' and whose interpretation is that of indirect speech:

10. a. Bonnie-sh chuy-k-'ish-'a
   Bonnie-Sj marry-**k**-say+sh-hearsay
   '(They said, I hear tell) Bonnie got married'

   b. *Bonnie-sh* *chuy-k uu'ish-k*
   Bonnie-Sj marry-k say+Pl-Asp
   'They say Bonnie got married'

There is a fundamental difference between the evidential markers of American Indian or Tibeto-Burman languages and those of languages spoken in South Eastern Europe and Middle Eastern Asia (such as Albanian, Bulgarian, Macedonian, Iranian, and Turkish) which have forms derived from perfects and resultatives and generally identified as indirect evidentials. These are areas where analyzing these verb forms is often highly complex. This raises the question of whether these languages have the category of evidentiality. For instance, in Turkish, the inflectional marker *–mIş* originates in perfect forms and is the grammatical means of referring to hearsay, inference, or perceived information on the basis of traces or result; it contrasts paradigmatically with the unmarked past *-dI*: in the opposition *-dI/-mIş gel-di* 'has come/came' vs *gel-mIş* ('has obviously come/obviously came'), *-dI* past exhibits "always neutral uses in cases where the speaker considers the evidential distinction inessential" (Johanson 2003, p. 275). Although specification of the information source is not crucial in Turkish, Johanson (2000, 2003, p. 374) explicitly states that "the notion of indirectivity is in accordance with the cross-linguistic definition of evidentiality" and treats it as an evidential category. In Aikhenvald's classification, Turkish has a binary system ('with two choices') of the subtype nonfirsthand versus everything else.

The situation in Balkan Slavic is more complex because new paradigms of aspect-tense forms developed out of the old perfect. While Macedonian never uses the third person auxiliary in aspect-tense forms based on the *l*-participle (Friedman, 1986, 2000), the auxiliary *săm* 'be' can be used or omitted in the third person in Bulgarian, as shown in the following examples: *Toj se prestoril* (renarrative aorist) *na umrjal* 'He pretended to be dead (I am told)' and *Toj se **e** prestoril* (aorist 'conclusivus') *na umrjal* 'He has pretended to be dead (I infer)'; *Toj se prestruval* (renarrative imperfect) *na umrjal* 'He was pretending to be dead (I am told)' and *Toj se **e** prestruval* (imperfect 'conclusivus') *na umrjal* 'He must have pretended to be dead (I infer).' Although the precise function of the auxiliary's omission or presence continues to be a matter of some controversy, Bulgarian cannot be reduced to a Turkish-type binary system: it does not fit into the evidential subtypes 'firsthand and nonfirsthand,' nor in 'nonfirsthand and everything else.' The auxiliary's omission or presence typically involves the speaker: the statement is made on the basis of hearsay, rumor, report, folk tales, and narrating history (auxiliary omission) or on the basis of reasoning leading to formulating a plausible explanation of tangible evidence and can be used for reconstructing facts that are not observed (auxiliary presence).

The basic issue with regard to evidentiality is to find criteria for characterizing the concept of evidential. Anderson (1986) was the first to point out that not all forms that have been called 'evidential' share a common set of 'evidential functions.' He proposes four parameters to identify a true evidential as a specific grammatical phenomenon (Anderson, 1986, pp. 274–275): (a) Evidentials show the kind of justification for a factual claim which is available to the person making that claim […]; (b) Evidentials are not themselves the main predication of the clause, but are rather a specification added to a factual claim ABOUT SOMETHING ELSE; (c) Evidentials have the indication of evidence […] as their primary meaning, not only as a pragmatic inference; (d) Morphologically, evidentials are inflections, clitics, or other free syntactic elements (not compounds or derivational forms). Commenting on Anderson's four criteria, Aikhenvald (2003, p. 24) and Boye and Harder (2009) criticize some of them, but not for the same reasons: Aikhenvald because 'the distinction between inflectional and derivational categories is not clear-cut' (cf (d)), and Boye and Harder (2009) because they adopt a functional-cognitive approach and give arguments "based on diachronic data exemplifying one of the paths of development that gives rise to evidential elements" (p. 17).

Evidentials can have various origins (Aikhenvald, 2004, pp. 271–302); they may come from the grammaticalization of lexical categories, verbs, deictic and locative markers, or other word classes.

Reportives are very often derived from a verb of 'saying' and are used in dialogue as well as in tales and myths. In Lezgian (North Caucasian), the reportive suffix *-lda* is derived from the construction *luhuda* 'one says' (Haspelmath, 1993, p. 148). In Tibetan, the reportive *-sa*, is derived from the verb *zer* 'say.' In Makah, the suffix *wa:**t*** is a reconstructed passive

form of the verb *wa·* 'say;' (9b) is opposed to (9a) and expresses an indirect message (Jacobsen, 1986, p. 17):

9. a. *xu.bitdib$^{?}$**u***
   'He was snoring'

   b. *xu.bitdibit**wa.d***
   'He was snoring (I was told)'

Perception verbs are a source of visual and non-visual evidentials. In Maricopa, a Yuman language (Vauprés region, Colombia, and Brazil), the visual suffix *'yuu-* comes from the verb *yuu-k* 'see' (Gordon, 1986, p. 85). In Wintu, *-nt^{h}er* is a passive form of the perception verb *mut-* 'hear, feel, sense, and perceive' (Schlishter, 1986, p. 49). From a diachronic point of view, the Tuyuca visual is a 'relic auxiliary verb' from 'seem' or 'be perceived' (Malone 1988, p. 132). In Tariana, the visual *-nuka*, *-naka* is related to the first person singular form of the verb *-ka* 'see,' while *-mha* comes from the verb *-huma* 'hear and feel' (Aikhenvald, 2004, p. 274). The source for nonvisuals may be verbs meaning 'seem, be perceived, and feel,' for example, in East Tucanoan languages (Aikhenvald, 2003).

Verbs referring to existence and location as well as demonstrative pronouns can participate in developing evidentials. In Wintu, the experiential evidential *?el* is probably "a morpheme meaning something like 'it exists'" (Schlichter, 1986, p. 54).

Over the last decade, evidentiality has been defined as a functional-conceptual substance domain (Boye and Harder, 2009), a conceptual domain (Wiemer, 2010), and a semantic-functional domain (Diewald and Smirnova, 2010). As a result, evidentiality has been extended to 'languages traditionally considered as unaffected' by it (Squartini, 2008) and includes a range of devices in order to establish the functional grounds for a cross-linguistic analysis: adverbial expressions such as *reportedly, supposedly*, or *allegedly* in English; mental verbs such as *penser* think,' *trouver* 'think, judge,' *avoir l'impression* 'have the impression' in French (Dendale and Bogaert, 2007) or Eng. *think, suppose, find, claim.*); parentheticals such as Fr. French *dit-on* or *paraît-il);* particles referring to a verbal report (Wiemer, 2010); Fr. *selon*, Eng. *according to*, Russ. *Soglasno*, Bulg. *už, kaj, spored*, Georg. *mixedvit, tanaxmad, cnobit*, and so on. Given the broad variety of linguistic phenomena, it is difficult to define unambiguously the notion of evidentiality. To some extent, however, there is a real problem here: if '[e]vidential meanings range from lexical to grammatical functions' (Diewald and Smirnova, 2010, p. 1), the question is: 'how wide this range can be?'

Recently, (ad)mirative meanings have received a lot of attention and are the subject of growing interest. Such meanings arise when the speaker is confronted with an unexpected discovery and expresses the contrast between the expected situation and what actually happens ('I did not know that S (but now I do)'). The term admirative was first introduced by Dozon (1878) in Albanian (for the history of the term 'admirative,' see Friedman (2012) and references cited there). Admirative usages expressing surprise at a newly discovered fact are well known in Balkan Slavic, Turkish, and other Balkan languages (see also Gerdžikov, 1984 for discussion on their theoretical status in Bulgarian). The notion of mirativity, introduced by DeLancey (1997), and its status as a grammatical category has recently been discussed in the journal *Linguistic Typology* (2012/13).

Evolution and Language: Cultural Transmission

Bill Thompson and Kenny Smith, The University of Edinburgh, Edinburgh, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Language exhibits a variety of structural properties that require evolutionary explanation. Many of these properties may result from processes of cultural evolution in populations of language learners. We review several key examples of how cultural transmission can lead to the emergence of linguistic structure, and outline the implications for evolutionary accounts of the origins of language.

Human language exhibits two remarkable and apparently contradictory properties. On the one hand, language is unique in the natural world, it is universal among our species, it displays striking complexity, and it has, by facilitating the development of complex social and technological systems, enabled humans to spread to all corners of the planet, and even out into space. From this perspective, language looks like a biological adaptation, which evolved in humans (and only humans) as a result of the fitness payoff associated with communication and information sharing. On the other hand, language is acquired incrementally through learning, it exhibits tremendous cross-cultural variation, and this variation poses no problem for the acquirer who could, as far as we can tell, master with equal confidence any existing language just by dint of exposure from birth. These properties might equally lead us to believe that language is a cultural trait, transmitted through social learning.

We can begin to reconcile these intuitions by acknowledging that language is the product of an interaction between two evolutionary systems: biological and cultural evolution. Recently, several independent findings have lent support to the view, which we favor here, that many of the defining characteristics of language can be explained largely as products of cultural evolution, with biological evolution having less to say about the specific structural properties of language. Debate has been reignited on whether there are truly any universal features of language, or whether these universals (typically taken as indicative of a species-wide 'language instinct') may be far fewer than has previously been supposed (Evans and Levinson, 2009). New techniques for reconstructing language histories (*see* Evolution and Language: Phylogenetic Analyses) suggest that, while large groups of languages do share features, these shared bundles of properties tend to pattern like products of shared cultural history, rather than biologically dictated behavioral universals (Dunn et al., 2011). In parallel, the biological basis for language has been questioned on evolutionary grounds (Chater et al., 2009), and on the basis of new evidence for plasticity in the functions of brain regions (Bedny et al., 2011). This shift in thinking has drawn attention to the need for a comprehensive understanding of how cultural process might give rise to the many observable properties of language, and, in turn, how these cultural processes might interact with biological evolution to shape the evolution of language and its cognitive underpinnings. A considerable body of research, involving (among others) linguists, biologists, psychologists, cognitive scientists, and computer scientists, is now dedicated to exploring the workings of the cultural evolution of language. Among the most basic questions underpinning this research agenda is that of the *problem of linkage*: namely, how do properties of individual learners give rise to population-level phenomena that we see in language? In simple terms: what kind of mechanism would allow individual language learners and users to unconsciously coordinate and produce a richly structured system of conventions shared throughout an entire population?

Cultural transmission is just such a mechanism: languages are transmitted by iterated learning, which is one type of cultural transmission, whereby learners acquire a behavior by observing similar behaviors in others who acquired those behaviors in the same way (Kirby et al., 2008). In the following two sections, we will present evidence, obtained through computational, mathematical, and experimental models of iterated learning, that processes of learning and use can lead to the emergence of linguistic systems that exhibit some of the fundamental features of human language. In the final section, we will turn again to biology, and discuss how this improved understanding of the potential role of cultural transmission and cultural evolution in shaping language might inform our understanding of how the human capacity for language evolved.

Language Transmission and the Evolution of Linguistic Structure

Hockett (1961) famously identified a set of design features thought to characterize the fundamental properties of language. Among these is the fact that language is *traditionally transmitted*, or passed from generation to generation through the mechanisms of vertical and oblique cultural transmission. (The distinction between vertical and oblique transmission rests on whether transmission is from parents to offspring (vertical), or from nonparental individuals (oblique). For simplicity, we will collapse this distinction, and refer to intergenerational transmission as vertical.) Vertical cultural transmission is analogous to genetic transmission in biology, and describes the transfer across generations of heritable traits: analogies between the cultural evolution of language and the biological evolution of species have been debated

since Darwin. While the study of language change and phylogenetic relationships between languages has been one of the longest studied subfields of linguistics (Grimm, 1819), only recently has a research program emerged to explore whether processes of cultural evolution arising from traditional transmission might be responsible for some of the other design features of language that Hockett identified. Perhaps the most influential methodology assumed in this framework is the use of computer simulations and mathematical models. Similar techniques have a long history of productive application in analogous topics of biology, and have been successfully modified for application to general models of cultural transmission in foundational research into social learning.

The evolution of language is a special case of cultural evolution due to several special properties that characterize its form and its transmission. In large part, these special properties stem from the fact that language is acquired through a procedure of inductive inference far more demanding than that required by other instances of social learning. Models of iterated learning explore the consequences of this kind of cultural transmission. Central to this approach is the concept of *learnability* (Brighton et al., 2005a,b). In principle, languages can vary with respect to the fidelity with which they are transmitted: some types of language might be more learnable than others. As a result of that variation, through cultural transmission some types of language may come to be more common than others, due to differential retention of different language types (or, more likely, different features within a single language). Computational and mathematical modeling allows the researcher to formally define the properties of such a system, and to study its behavior systematically. This approach has shown how the cultural transmission of language can explain the existence of several of the structural properties fundamental to language. One such structural property is *compositionality*. A communication system is compositional if, for a given complex signal, the meaning of that signal is a function of the meanings associated with the component parts of the signal, and of some set of rules that determine how those component parts can be combined. This is true of all human languages: put simply, in language, the meanings of a sentence are composed from the meanings of the morphemes, words, or phrases that make up that sentence. These component parts are put together in accordance with systematic rules that govern the patterns of legal combination and the meanings of those combinations. Taken together, these properties form the basis of syntactic structure in language. Compositionality is a universal, definitional feature of human language, but it is not present (as far as we currently know) to any great extent in the communication system of any other animal (The waggle dance of bees (von Frisch, 1974) and the alarm-calling system of Campbell's monkeys (Zuberbuhler, 2002) show that some minimal, tightly constrained form of compositionality does occur in animal communication, but there is a clear difference between these systems and the massively productive use of compositionality in human language.). If any property of language were to seem straightforwardly and plausibly attributable to a biologically evolved faculty of language in humans, it would be compositionality, since it is compositionality that gives language its open-ended expressive power. However, models of iterated learning have shown that there exists a preferable alternative explanation for this linguistic universal: compositionality can emerge as a result of cultural transmission, without this specific property of language needing to be hardwired into language learners.

This explanation relies on an age-old philosophical observation concerning the nature of learned behavior, traditionally treated as evidence for the necessity of innate knowledge, known in contemporary terms as *the poverty of the stimulus*. The poverty of the stimulus describes the idea that learners of a language, among other challenges they face, are exposed to only a subset of the language they are attempting to learn. While this argument has taken various forms, many controversial, there is at its core an incontestable truth: language is open ended and productive, encoding in grammar the capacity to generate a potentially infinite number of legal sentences, yet the learner's exposure is necessarily finite, not least because of a finite lifespan, but also because language acquisition is largely complete in the first decade of that life. In other words, you cannot see a language in its entirety before you learn it, because all languages are infinitely large. While this transmission *bottleneck* is sometimes presented as a logical argument demonstrating the importance of innate knowledge in language-learning, the cultural evolution perspective treats the poverty of the stimulus as a *selective pressure* facing the evolving language: the poverty of the stimulus presents a pressure for languages to be reconstructable on the basis of incomplete data. Languages, or parts of languages, which evidence their full structure in a greater proportion of their utterances will be more faithfully transmitted than languages whose utterances are less representative of the whole. One way a language can achieve this is by employing structural regularity in the mappings between meanings and signals.

Consider three possible kinds of language that provide different ways of mapping meanings to signals. A maximally *holistic* language employs a unique, undecomposable signal for every possible meaning. A maximally *underspecified* language would employ the same signal for every possible meaning. An ideal compositional language, unlike a fully underspecified language, provides a distinct signal for every meaning: however, unlike a holistic language, those signals are constructed via a rule-governed, compositional process of the sort described in this article, where the structure of the meaning is reflected in the signal. Figure 1 contrasts examples of these different kinds of mappings. What challenges would these systems pose to a learner?

To acquire the full holistic system, a learner must observe *all* meaning–signal mappings: no generalizations can be drawn from exposure to a subset, since by definition the holistic language offers no generalizations about how meaning and signal are related. Such a language would therefore be unlearnable from a subset: while you might be able to reproduce the (infinitely small) fraction of the language you witnessed during your lifetime, you would not be able to produce or interpret utterances you had not already encountered. In contrast, to acquire a fully underspecified system, the learner need only observe one pairing of meaning and signal: from a single observation, the learner can make accurate generalizations about the rest of the system. Acquiring a fully underspecified language in the face of a bottleneck on transmission is therefore

Figure 1 Three ways to map between meanings and signals. (a) Holistic mapping: little correlation between the forms of meaning and signals. Neighboring meanings do not necessarily map to neighboring signals; (b) a compositional mapping between meanings and signals. Here, there is a correlation between the form of a meaning and the form of a signal, such that exposure to a subset of these mappings will allow the learner to induce a strong generalization; (c) a maximally underspecified mapping: all meanings map to the same signal.

easy: to put it another way, underspecification is adaptive in the face of a transmission bottleneck. Various computational simulations of the iterated learning process show that, purely as a result of cultural transmission, underspecified languages will evolve: the most stable, learnable, transmissible system is a fully underspecified system (Brighton et al., 2005a,b). All that is required for this to happen is that learners are able to make inductive leaps: to go beyond that which is exemplified in linguistic experience and draw piecemeal generalizations not directly evidenced in their data and not previously present in the linguistic community. In its most general conceptualization, this amounts to a bias toward *compressed representations*: a preference for simple grammars, exploiting those generalizations that the data afford. Iterated learning with a bottleneck inherently favors generalization, but can actually lead to generalization only if learners are capable of drawing such generalizations, or compressing information. These conditions alone lead to the cultural evolution of maximally learnable, maximally underspecified languages: generalizations (of the form "several meanings can be expressed using the same signal") emerge and spread, until a single generalization ("*all* meanings are expressed using *this* signal") takes hold.

However, language is not maximally underspecified; it is compositional. From the perspective of the learner, compositional languages lie somewhere between these two extremes. Unlike fully underspecified languages, they require a substantial body of data to learn: you need to see enough data to figure out the rules and regularities that relate signal to meaning. However, unlike holistic languages, you do not need to see the full system provided you get enough data to work out the compositional system for producing and interpreting signals, you can reconstruct the whole language, or produce or interpret signals you never actually encountered during learning. Like maximally underspecified languages, compositional languages require learners who are capable of making the generalizations that data from a compositional language suggest. However, if compositional languages are to evolve through transmission, an additional bias must be in place: the evolution of compositional language relies on the presence of some bias against many-to-one meaning–signal mappings. That is, alongside the pressure for learnability, there must exist in the system some pressure against underspecification. A learning bias against many-to-one mappings (i.e., an antiambiguity bias) is a simple way to implement this pressure in simulations, and this kind of bias is empirically motivated by psycholinguistic research (e.g., see Brighton et al., 2005a,b for review; also, this article further discusses the use of language for communication as another pressure against underspecification). In summary, vertical cultural transmission in populations of learners who are biased to form compressed representations of their experiences, and to avoid underspecification, leads eventually, in the absence of any biological change, to the evolution of languages governed by (rudimentary) syntactic structure, where before there was none. On the grounds of parsimony alone, an explanation of this kind seems preferable to assuming that compositionality is a reflection of a hardwired constraint in learners.

Current theoretical work in this tradition is grounded on two major agendas: to explore whether other fundamental properties of language can also be explained as products of cultural evolution, and to search for general principles of language evolution through cultural transmission. Pursuing the former agenda, comparable accounts, similarly based on biased cultural transmission, have been offered for various other aspects of linguistic structure: most research so far has been concerned with the origins of syntactic phenomena, such as embedding and recursion (Batali, 2002; Kirby, 2002), constituent-order patterns (Kirby, 1998), and morphosyntactic regularity and irregularity (Kirby, 2001), although some researchers in the iterated learning model (ILM) tradition have also studied the cultural evolution of phonological (Boer, 2001) and semantic systems (how sound systems or word meanings evolve) (Perfors and Navarro, 2011).

Research focused on the more general principles of the cultural evolution of language aims to abstract away from specific instances and define the foundations of cultural transmission through inductive inference. Current work is mostly situated in the rational tradition and based on the principles of Bayesian learning (Griffiths and Kalish, 2007). Bayesian models of iterated learning have various merits: principally, this approach facilitates a high degree of abstraction, allows precise treatment of the role of bias in individual learning, and draws useful connections between models of language evolution and computational techniques heavily studied in the Artificial Intelligence and Machine Learning literature. A major objective of Bayesian ILMs is to establish the abstract link between properties of individual learners and population-level phenomena: do individual learning biases, such as those discussed in this article, straightforwardly determine the kinds of languages we see in human populations? If the answer to this question is yes, then typological universals, or in fact behavioral universals of many kinds, can act as a reliable map of the structure of

the mind. If the answer is no, and cultural transmission can amplify or wash out the effects of learning biases, such that the relationship between biases of individuals and universals is complex, then it may be a mistake to infer cognitive universals from typological generalizations.

As a first approximation, there is a consensus (supported by classic mathematical analyses of cultural evolution) that cultural evolution amplifies individual biases, introducing opacity in the relationship between properties of individuals and properties of cultural systems: put simply, just because we see a strong skew in the distribution of some cultural trait (say, a linguistic trait) across human populations, or even an apparently universal trait, we cannot conclude that, that reflects a strong or absolute constraint in individuals: it could be a consequence of a far weaker bias in individuals, amplified over many generations of transmission (Boyd and Richerson, 1985; Kirby et al., 2007). A significant finding to emerge from Bayesian analysis of Iterated learning is that under certain conditions, this general tendency may not hold: for a particular class of psychologically plausible learning algorithms, Iterated learning converges to a state entirely determined by the biases of individual learners (Griffiths and Kalish, 2007). This result demonstrates that relatively minor differences in our assumptions about the kind of learning mechanisms that learners employ can lead to dramatically different evolutionary hypotheses. It is not yet clear which pattern of results better characterizes the transmission and evolution of language. Much current work is motivated by this problem: aiming to determine systematically which conditions give rise to which pattern of linkage, by exploring alternative models of individual learning and by manipulating aspects of the transmission process such as population structure and transmission dynamics.

Alongside this approach has emerged another new methodology, intended to bypass the problems involved with making assumptions about the nature of learning biases: language evolution experiments with human participants. Language evolution experiments in the laboratory combine artificial language-learning techniques (Gomez and Gerken, 2000) with diffusion chain experimental techniques (Mesoudi and Whiten, 2008; Whiten and Mesoudi, 2008) to replicate and manipulate the process of iterated learning. Artificial language-learning experiments involve training participants on an experimenter-constructed miniature language and subsequently testing their knowledge of that language, often by eliciting productions. A diffusion chain is a simple laboratory model of cultural transmission, where the productions of one participant constitute the training input to the next participant, creating a chain of learners through which information is diffused. Language evolution experiments in the laboratory are in their early stages, although some fundamental findings have already emerged, and some important parallels between models and experiments are worth highlighting.

One early series of experiments replicates closely the simulation models of the emergence of compositionality discussed in this article (Kirby et al., 2008). In these experiments, participants are trained on pairs of associations between orthographic strings (written words of an artificial language) and sets of meanings, or objects, whose features vary along several dimensions (color, shape, and motion: e.g., a spinning red square or a bouncing blue triangle). The first participant in each diffusion chain is trained on mappings generated at random: each object is paired with a random word, so no regularities exist in the mappings (i.e., the language is holistic). After a short period of testing, the participant's knowledge of the language is tested by eliciting productions, whereby the participant is prompted to produce a string for an object. Some of these test trials will involve objects encountered during training paired with a label, but the test set also includes novel objects: participants may be prompted to produce labels for objects they have never seen before. In other words, as in the models, there is a bottleneck on transmission, forcing learners to attempt to generalize from the parts of the language they encountered during training. These productions then form the data with which the next participant is trained. This procedure is repeated, and the properties of the artificial language are tracked down the chain. As in the theoretical models, the pressure introduced by the bottleneck (and also participants' fallible memories; Cornish, 2010) creates an advantage for generalizable languages that can be more comprehensively reconstructed from exposure to a subset: the more a learner is able to make generalizations, the less likely it will be that novel items during testing will disrupt the transmission of the language to new learners. Experimental findings confirm that under these conditions, a culturally transmitted language evolves to become highly learnable: after only a few generations, the artificial language is largely underspecified,

Figure 2 Experimentally evolved artificial languages. (a) An evolved language with a systematically underspecified mapping from meanings to signals; (b) an evolved compositional language. Reproduced from Kirby, S., Cornish, H., Smith, K., 2008. Cumulative cultural evolution in the laboratory: an experimental approach to the origins of structure in human language. Proceedings of the National Academy of Sciences of the United States of America 105 (31), 10681–10686.

employing a small repertoire of homonyms to cover a much larger space of possible meanings (see Figure 2(a)).

In a subsequent experiment, the data were manipulated as they were passed from participant to participant, such that any ambiguous signals in a participant's productions were removed by the experimenter before those productions were fed to the next learner in the chain. The motivation for this interference is twofold: first, equivalent theoretical models predict that to prevent an evolving language from collapsing to underspecification, some bias against homonymy is necessary, as discussed in this article. Since, at least in this task, no such bias appeared to be expressed by participants (or, rather, any such bias is very weak given the contracted training period and the strong requirement for generalization introduced by the transmission bottleneck), the experimental manipulation imposes an equivalent influence. Second, this manipulation can be taken as a proxy for the effects of language *use*. Presumably, in the real world (but not in this simple experiment), the requirement of language users that their language can be used to communicate imposes a strong pressure for expressivity in language: maximally underspecified languages are maximally useless for communication. Again, as predicted by the models, under this regime, the artificial languages develop a compositional structure (see Figure 2(b)): competing pressures for learnability and expressivity conspire to produce systematically structured compositional languages. The pressure for learnability is evidently due in large part to systemic properties of vertical cultural transmission. The pressure inhibiting underspecification, however, may be driven by biases of learners (as assumed in some models; e.g., Smith, 2004), or it may have its roots in another process: intragenerational, or *horizontal*, cultural transmission.

Language Use, Negotiation, and the Formation of Conventions

Broadly construed, language is a fundamentally social phenomenon: we use it to inform, amuse, impress, coerce, or cajole other people. Unsurprisingly, some of language's key features have received explanations that appeal to dynamic social interaction, in a manner comparable to the literature reviewed in this article explaining compositionality in terms of language-learning and transmission. A well-studied example, which is general enough to have implications for many aspects of language structure, is the emergence of *convention*. Communication relies on convention at all levels of language structure: in order to be communicatively useful, linguistic conventions must be shared by an entire linguistic community. How do conventions, particularly linguistic conventions such as a shared name for an object or a shared grammatical device for signaling some more abstract concept, arise in a population? This is a question about the nature of cultural transmission, since the processes by which individuals influence each other as they interact are questions about culture.

As with vertical cultural transmission, computational simulations and mathematical analyses of conventional alignment have produced useful insights. In principle, shared conventions can emerge from nothing and propagate rapidly (i.e., within a single generation) (Steels, 2011). That is, a population of learners who share no system of conventions can easily negotiate and maintain such a system culturally. The speed and accuracy with which populations converge, and the stability of an emerging system, depend crucially on the particular cognitive abilities assumed of learners. Simple capacities for memory and invention are sufficient to allow populations to maintain shared conventions, although these end up containing much interindividual variation, and are therefore communicatively suboptimal. Slightly more complex assumptions about how learners deal with competing conventions, known as strategies for *lateral inhibition* (equivalent to the biases against many-to-one mappings discussed in the Language Transmission and the Evolution of Linguistic Structure section), are necessary for optimally functioning conventional systems to emerge (Steels, 2011). Nevertheless, convention negotiation as a phenomenon may well underpin many aspects of linguistic structure: topics studied in this framework range from the lexicon, to syntactic constructions, to phonemic inventories, and to even more fine-grained systems such as case marking and paradigms for marking tense. We now have a clear understanding of how this kind of agreement can emerge culturally in populations, supported by evidence from agent-based computational simulations, mathematical analyses, and even robotic experiments (Steels, 2011).

Again, alongside theoretical and computational analyses, there exists a body of complementary experimental research on human participants. One strand of research in this area explores the emergence of another fundamental design feature of language: arbitrariness. At least to a first approximation, linguistic conventions are arbitrary. This is clearest in the case of words, which do not seem to resemble the things (objects, actions, or ideas) to which they refer: for instance, the English word 'tree' shares no obvious properties with the plants to which it refers (it is not tall, or green, and it does not sound like a tree creaking in the wind or irresistibly evoke the smell of crushed pine needles). We can imagine a language that is nonarbitrary: indeed, there might be advantages to such languages. For instance, a system of *iconic* signs (e.g., words or gestures that sound or look like the thing they refer to) would allow naïve users to straightforwardly understand and even produce novel signs.

A recent series of psychological experiments shows how conventionalized signs can emerge, and how from iconic beginnings those signs gradually become less and less iconic as a result of their transmission and use (Fay et al., 2010; Garrod et al., 2007). In the classic version of these experiments (Garrod et al., 2007), pairs of participants engage in a graphical communication task similar to the popular game Pictionary: they use drawings (i.e., not their preexisting symbolic language) to communicate about concepts or objects taken from a prespecified list, playing many such games repeatedly with a single partner. Initially, the communicative drawings tend to be highly iconic (e.g., if attempting to convey 'computer monitor,' you might do your best to produce a good drawing of a computer monitor, base unit, keyboard, etc.: see Figure 3). However, when pairs interact repeatedly (i.e., they try to communicate the same concepts several times), the emergent signs tend to become abstract and

Figure 3 The evolution of a signaling system. Depictions begin highly iconic and over interactions approach arbitrariness. Reproduced from Garrod, S., Fay, N., Lee, J., Oberlander, J., MacLeod, T., 2007. Foundations of representation: where might graphical symbol systems come from? Cognitive Science 31 (6), 961–987.

arbitrary: rather than drawing the computer monitor, you might produce just an inverted U shape (see Figure 3) and be confident your partner knows what you mean. Because pairs have a shared cultural history and memory, their signing systems need not iconically depict their referents: each member of the pair knows the evolutionary history of the sign (e.g., that the inverted U resembles the base unit that you drew when you first produced an iconic drawing for 'computer monitor'), and so the signs themselves are free to become less iconic and more (seemingly) arbitrary. Iconicity in the system gradually deteriorates, in favor of simpler, more efficient conventions that nevertheless pick out specific objects or concepts. Onlookers, who try to identify the depicted object using these abstract signs without being exposed to the shared interaction history, are at chance, although a follow-up study (Caldwell and Smith, 2012) shows that witnessing these signs being used communicatively is sufficient to allow naïve individuals to adopt them as purely arbitrary signaling conventions, without access to the historical process by which those particular signs became established. Interaction and transmission are the keys: a simple process of social negotiation and cultural evolution can explain how an initially iconic signaling system can quickly become one of arbitrary, symbolic conventions. Similar phenomena are documented by fieldwork exploring emerging sign languages, although this too is a young enterprise (Sandler et al., 2005).

Coevolution: A Brief Word

The examples discussed so far are not exhaustive – other aspects of language structure have received explanations that draw heavily on cultural processes – and of course much remains to be done: we are far from offering a complete explanation of language in cultural terms. However, it is clear that there exist viable cultural explanations for the evolution of many of the most fundamental design features of language, including compositional syntax, word-order generalizations, morphological regularities, recursion, phonological regularities, shared expressive conventions, and arbitrary reference. The findings of this research enterprise raise profound questions about the role of biological evolution. If many important features of language could have arisen through cultural processes, what is left for biology to explain?

While it is important to draw a marked distinction between the biological evolution of the language faculty and the cultural evolution of languages themselves, it is a mistake to treat biological and cultural processes as independent: neither acts in isolation, and both feed into each other, acting together to create a coevolutionary system. To be clear, we cannot entertain cultural explanations for language without appealing to the mechanisms of learning and the inductive biases that underpin them (although the link between the bias and the details of the linguistic structure may be obscure). And bias is a topic for biology, where we isolate the need for cognitive bias, we identify a contribution of biology, and of the selective forces that maintain useful traits. Similarly, at least from some perspectives (Scott-Phillips et al., 2011; but see Laland et al., 2011 for a response), any appeal to biological adaptation in fact subsumes the cultural approach: natural selection pervasively exploits environmental regularities that play a part in boosting an organism's fitness. In principle, cultural processes are just one more environmental regularity that biological evolution can commandeer: where cultural processes do the work, we should expect this to be reflected in biology.

At present, very little is known about how these two processes interact to shape language. Preliminary research (Smith, 2004; Smith and Kirby, 2008) suggests that these interactions are nontrivial: opaque mappings between individual biases and population-level cultural phenomena may significantly constrain the kinds of adaptations that can arise through natural selection to support language and other cultural systems. If these indications are accurate, theories of linguistic nativism (a class of theoretical perspectives that hypothesize innate knowledge of linguistic structure) may have to be reconsidered on evolutionary grounds: rather than supporting the existence of a language faculty built around rich innate knowledge of linguistic structure, evolutionary reasoning might instead suggest biological underpinnings of language that are composed of the preadaptations necessary for the processes of cultural evolution.

Summary

Here, we have outlined the perspective that cultural evolution is a major force driving the emergence of structure in human language. Cultural evolution results from various kinds of cultural transmission: learning and use are two forms of transmission in particular that influence the nature of language. Many aspects of linguistic structure have received explanations that rely heavily on these processes, and many more remain to be explored in this way. This perspective is supported by evidence from computational, mathematical, theoretical, and experimental sources, which continue to inform our understanding of the origins and evolution of language, and to raise important questions concerning the evolutionary processes that shape human behavior.

Abstract

The close relationship between biological evolution and language was noted by Darwin himself in an oft-quoted passage from *The Descent of Man:* "the formation of different languages and of different species, and the proofs that both have been developed through a gradual process, are curiously parallel" (Darwin, 1882). In fact, the development of evolutionary theory in biology was inspired in part by the advances in historical linguistics in the early nineteenth century. In the twentieth century, evolutionary theory did not have much influence on linguistics, in part due to the advent of structuralism and the focus on synchronic linguistic analysis. In the past two decades, there has been a considerable increase in interest in the relationship between language and evolution. The interest has been manifested in three areas of recent research. The first is the evolutionary origin of the human language capacity, a topic that was actively avoided in linguistics for a century. The second is the employment of techniques of phylogeny reconstruction from biology in the analysis of genetic families of languages. Finally, there is the application of theories of evolutionary processes to language change, based on the hypothesis that, as Darwin wrote, the two are strikingly parallel.

The Evolutionary Origin of Language

The evolutionary origin of language is not technically an example of parallelism between biological evolution and language. It simply is an instance of biological evolution, specifically the evolution of a behavioral capacity in one particular species. This topic was avoided in linguistics for over a century because of the absence of empirical evidence about any stage of language prior to modern human language.

All modern human languages are general-purpose communication systems of a similar order of complexity; there is no reason to believe that any contemporary human languages represent an earlier stage in the evolutionary development of the language capacity. Written records of language are very recent – no more than 5000 years old – and they make clear that languages of that age are no different from contemporary human languages (*see* Writing, Evolution of). Languages otherwise do not leave material evidence, so the archaeological record leaves no direct record of the evolution of the language capacity.

Evidence from hominin skeletal remains suggests that there have been anatomical changes that indicate the increased ability of our ancestors to produce a wide range of vocalizations, and to control our breathing in such a way to produce linguistic sounds. It is generally assumed that the ability to produce a rich variety of vocalizations implies the existence of language at the time of these anatomical changes. However, it could be that such vocalizations had other functions than a general-purpose communication system, such as music and ceremony, or that the sort of language that such vocalizations were used for was quite different in its structure and communicative range than modern human language. Likewise, the great expansion of brain capacity in the development of humankind is an indicator of the emergence of the cognitive capacity for modern human language. But lacking more specific details of neural structure in hominins, this change cannot tell us more about the evolutionary origin of the human language capacity.

The taboo against studying the evolutionary origin of the language capacity has now fallen. A number of different approaches have been taken to tackling the question. All of them are necessarily indirect. Two of the commonest approaches are computer-based models simulating a society of interacting agents, to explore under what circumstances language structures might emerge (e.g., Kirby, 1999); and comparative ethology, comparing the communicative, symbolic, and interactional capacities of our nearest relatives, the primates, and other species that possess vocal communicative systems, such as various species of birds and cetaceans (e.g., Tomasello, 2008). Child language acquisition is also used as a reference point for language origins (Tomasello, 2008). Comparison to child language acquisition must be treated with caution because children learn language by being exposed to a modern human language, which will influence their course of development. Also, children largely already have the cognitive and social capacities of modern humans, so they do not represent the sort of hominins in which the modern human language capacity evolved. More recently, experiments using artificial language learning have come to be used in the search for language origins (*see* Evolution and Language: Cultural Transmission). Again, the subjects of artificial language learning experiments already have the cognitive and social capacities of modern human beings, and they also have knowledge of a modern human language at the point that they engage in the experiments. This latter point also applies to proposals about the origins of language based on more naturalistic examples of language 'creation,' such as pidgins, creoles, and certain sign languages.

Many earlier studies focused on the structure of the linguistic signal. In comparative ethology, the question was whether or not certain structures of human language utterances were unique, or could be found in the communication systems of other species. For example, it was claimed that vervet

monkey alarm calls were symbolic, in that they distinguish three different kinds of predators, and that bee dances and some bird songs involve a combinatoric syntax not unlike that of human languages. In the modeling approaches, the agents would produce strings of units and through simple rules of interpretation and feedback from such interactions, stable meanings of the units (i.e., symbols) and regular syntactic combinations were shown to emerge over several generations of interactions.

More recent studies have taken a broader perspective on the evolution of the human language capacity. Language structure does not evolve for its own sake, but only as part of a larger system of social interaction among human beings. Even the function of communication, often taken to be the raison d'être for language, actually serves the ultimate goal of achieving some joint action between persons. These joint actions form the basis of human culture and society. In other words, the evolution of language is part of the evolution of human social interaction and human culture (Tomasello, 2008).

This broader perspective implies, for example, that the computational modeling of the emergence of language will have limited success with disembodied agents simply reacting to whether a string of units refers to some object or not. In one modeling project from this perspective, the agents are robots that have perceptual and motor abilities, and the modeling includes visual processing and the establishment of joint attention on the part of the robots toward a potential referent for any utterance that is produced (Steels, 2011). Of course, this type of modeling is very ambitious, and requires solving problems in visual and auditory processing, motor activity, and social interaction as well as language structure processing and cognitive categorization and combination. In other words, one must model human beings in their full perceptual, motor, cognitive, and social abilities in order to model the emergence of language.

In the case of comparative ethological approaches, the broader perspective implies looking at the social behavioral capacities of primates and other species, including joint attention, reasoning about other individual's beliefs ('theory of mind'), coordination of actions, and the ability to engage in cooperative activity, as well as cognitive abilities of categorization, causal reasoning, and representing knowledge of displaced experience (i.e., not the 'here and now') that have been traditionally associated with the evolution of the language capacity. All of these social behaviors are preconditions for the evolution of modern human languages. Comparative studies suggest that many other species have the simple cognitive capacities listed above, but few if any have the social cognitive capacities required for language, and not to the degree that modern humans do.

Language embedded in its social interactional context is part of a very complex suite of human behavioral capacities. It is highly unlikely that this complex suite evolved suddenly. Thus, the transition to modern human language in the hominid lineage was probably a gradual one, with a number of intermediate stages of 'pre-language.' Unfortunately, there is still a great gap between animal communication systems known to us and modern human language, so just what those intermediate stages are is largely a matter of speculation. One common proposal is that there was a stage in which utterances consisted of only one symbolic unit (a one-word stage). Some argue that a multiword stage developed by combining these single units in a single utterance, while others argue that a multiword stage developed by reanalyzing the single symbolic unit (a complex vocalization) into meaningful parts. Other proposals are based on the functions of the linguistic units. An earlier stage may involve gestures that are indexical, establishing joint attention in order to coordinate joint actions; names for individuals and symbolic gestures that denote things or actions emerge in a later stage. Or an earlier stage may involve more direct interactions such as commands or questions; utterances whose sole purpose is to share information, especially about displaced experience, develop in a later stage. Such intermediate stages of pre-language only make sense in the context of plausible intermediate stages of social interaction between what is observed in other primates (or other species) and what occurs between human beings in contemporary societies.

The Use of Biological Methods for Language Classification (Phylogenies)

The most obvious respect in which biological evolution and language are parallel is that languages form lineages in much the same way as species do (*see* Evolution and Language: Phylogenetic Analyses). Languages have parents and daughters, and form trees of ancestors and descendants; these trees are called phylogenies in biology (*see* Comparative Method in Evolutionary Studies). In both domains, the ancestors are no longer present, because they have either become extinct or the ancestral species or language has split up into the contemporary species or languages. In only a few cases is there a material record of ancestral forms – fossil individuals of ancient species and written records of ancient languages. As a consequence, evidence for the phylogeny of both species and languages is indirect, namely, the traits of the currently existing species or languages. Comparative work among languages uncovers genetic trees, just as comparative work among species uncovers biological taxa. In some cases, historical linguists have arrived at conclusions about the nature of comparative historical analysis before biologists have. For example, an important principle of comparative historical linguistics is that a trait that is an innovation among daughter languages is more important evidence that the daughter languages form a subgroup than retention of a shared trait from an ancestral language. This principle was later independently adopted in the cladistic approach to constructing phylogenies (Hull, 1988).

Thus, both the basic fact – branching lineages – and the basic method – comparison of present-day members – are the same for biology and language. For this reason, recent work has increased in the application of phylogeny reconstruction methods from biology to language data (*see* Evolution and Language: Phylogenetic Analyses). For the most part, it has been biologists using these methods on language data, rather than linguists adopting these methods for historical linguistics. The basic reason for this fact is that the biological methods are essentially quantitative (and increasingly complex), while the methods of traditional historical linguists are essentially qualitative.

In comparative historical linguistics, the traits used to classify languages into genetic families (i.e., phylogenies) are words, that is, combinations of form and meaning. Words are particularly good traits to use for phylogenies. Words generally evolve independently of each other, so a large number of words represents a large set of independent pieces of evidence for a phylogeny. (In some cases, words are derivationally related, such as *long* and *length*, and so are not entirely independent.) The pairing of form and meaning is largely arbitrary, so other factors are unlikely to lead to convergence across languages. (There are cases of onomatopoeia, such as *meow*, but they are few and are avoided by historical linguists.) For this reason, historical linguists avoid schematic grammatical traits, such as subject-verb-object word order and the presence of grammatical gender. These traits are limited in their possibilities (much more so than the possible pairings of forms and meanings), and their presence is often due to universals of grammatical structure, of the sort studied in linguistic typology (*see* Linguistic Typology), rather than common ancestry of the languages that contain them. In biological terms, words are weakly filtered by selection but schematic grammatical patterns are not. Individual words form lineages themselves, but these word lineages bundle together, especially in basic vocabulary. This is what allows us to say that a language is the daughter of another language: most of its linguistic material comes from a single source. Of course, some words come from a language other than its parent; these are borrowings. Borrowings are more common in nonbasic vocabulary, although they occur in basic vocabulary as well. To the extent that borrowings can be identified and excluded from analysis, then the phylogeny of languages is tree like: a single parent and multiple daughters.

Most applications of biological methods in phylogeny reconstruction to language data begin with a set of words that are assumed to be cognate, that is, inherited from a common ancestor language (called a protolanguage). That is, for a set of languages, the data consists of whether or not some or all of the languages share a cognate for that meaning, for all the meanings in the word list. The phylogeny reconstruction algorithms use computational statistical methods to construct a phylogeny for the languages in question, given the distribution of cognate forms across the languages. These methods have increased in sophistication in recent years, aided by increases in computational power (e.g., Bouckaert et al., 2012; *see* Comparative Method in Evolutionary Studies; Evolution and Language: Phylogenetic Analyses).

The phylogeny reconstruction methods provide a more precisely quantifiable judgment weighing the evidence from the complex distribution of a large number of cognates. They have been applied to universally accepted, chronologically relatively shallow families such as Austronesian (in Oceania) and Bantu (in Africa) in order to clarify the subgroupings of those language families and provide support for hypotheses about the prehistoric migrations of the speakers of those languages. Such methods have their limits, however. For even a relatively small number of languages, the number of possible trees that can be constructed is far larger than the number that can be tested using current computing power. Hence, the phylogeny reconstruction algorithm can only test a small subset of the possible trees against the data provided by the list of cognate forms. (Much of the recent effort in refining phylogeny reconstruction algorithms is in how to explore the search space of possible trees.) One consequence of this fact is that a phylogeny reconstruction algorithm does not produce a single 'best' family tree; it produces a probability distribution of greater or less likely trees for the data.

Against this concern is the fact that even crude methods can find the major subgroups for the language families to which they are applied, such as the major subgroups of Indo-European. That is, the phylogenetic signal is very strong. But that signal is strong enough that visual inspection of cognate lists reveals those aspects of the phylogeny, and employment of quantitative methods is unnecessary. When it comes to resolving phylogenetic questions which are still a matter of debate among historical linguists, then the ability to find the most likely trees becomes an important issue in applying quantitative methods to historical linguistic problems.

Any list of cognates for a set of languages is going to give conflicting information about the phylogeny of those languages. Languages lose cognate forms; the original cognate changes meaning, or is lost entirely, and its form is replaced by another, unrelated form. Hence a missing cognate is not necessarily evidence that the language does not belong to the family in question. Deciding whether a set of cognate forms is a common innovation, justifying placing those languages into a subgroup, or a common retention, whose survival or loss is an accident, is not an automatic process. It requires balancing evidence from other cognate distributions to decide which cognates define a subgroup and which ones do not. The phylogeny reconstruction algorithms encode a particular way to make these decisions, based on their utility in biological evolution. The algorithm may or may not have the same utility in language change (this factor has not been discussed in the relevant literature).

The application of biological phylogeny reconstruction algorithms to language classification is actually a hybrid method. The data to which the algorithm is applied is already processed by a linguist: a linguist has decided which words are cognates and which ones are not. One of the chief problems in determining cognates is whether words that are similar in form and meaning across languages are borrowings or not. Some putative cognates may turn out to be borrowings. Some phylogeny reconstruction programs produce networks rather than trees. In most if not all cases in language history, ancestry vs contact are clearly distinct; for example, English is a Germanic language, albeit with many words borrowed via contact with French. Historical linguists look for patterns in the distribution of similar forms in order to differentiate common ancestry from borrowing. For example, similar forms across the bulk of basic vocabulary is indicative of common ancestry, whereas similar forms concentrated in particular semantic domains of nonbasic vocabulary (e.g., animal husbandry, religious ceremony) is indicative of contact; and a high degree of similarity of forms to the forms in just one language suggest that the latter language is the source of borrowing. Judgments based on differentiating types of vocabulary, or patterns of distribution across sets of languages, are not yet incorporated into phylogeny reconstruction algorithms.

What is of most interest to linguists (and nonlinguists) is the establishment of chronologically deeper language families than those widely accepted among linguists today. The

comparative historical linguistic method starts from languages that are accepted to form a group; phylogeny reconstruction algorithms do the same, by starting with cognates for accepted families. Deeper language families have been proposed, but are controversial among linguists. In principle, it is possible to create algorithms that would identify form–meaning similarities among a complete set of words across a large set of languages not accepted to be related; look for correspondences between the sounds occurring in equivalent positions in the words, which is strong evidence for cognacy; use distributional patterns of form–meaning similarities to differentiate likely cognates from likely borrowings; and use all of this information to postulate likely family trees. It is only very recently that the first efforts to devise such algorithms are being made.

Biologists interested in prehistoric human population history have compared phylogenies reconstructed from biological data to language family trees, and have observed parallels between biological phylogenies of humans (and the migration patterns they imply) and language family trees. The combination of biological and linguistic phylogenies has been used to clarify the prehistoric movements of Austronesian and Bantu peoples, where the language families are widely accepted; and the migration of Native Americans into the New World, where the language families that resemble the biological phylogenies remain controversial (Reich et al., 2012). The parallels between biological and language phylogenies do not necessarily match in all details, because human populations may give up their heritage language and shift to another language. Nevertheless, considering both biological and language families together gives us a more refined picture of human prehistory.

The Parallel between Biological and Linguistic Evolution

The fact that both languages and species form lineages, and numerous other parallels between biological evolution and language change, has led many linguists to discuss analogies between the two domains. Although observing analogies may provide inspiration for theories of language change in linguistics, they do not provide a principled basis for constructing an evolutionary theory of language change. In particular, when one finds a disanalogy between biological evolution and language change, it is unclear whether the disanalogy is due to simply a difference between the two empirical domains, or the disanalogy points to profound differences between biological evolution and language change. In fact, domain-general theories of evolutionary units and processes have been proposed. These theories are intended to subsume both biological evolution and some form of cultural evolution (*see* Cultural Evolution: Overview). There is major debate over the appropriateness of these theories; the following sections will briefly summarize the major issues.

Most biologists consider the fundamental principles of Darwin's evolutionary theory (Darwin, 1859) to continue to hold (*see* Darwinism). These principles are descent with modification and selection. Descent with modification leads to lineages, and occurs through a process that is now generally called replication. Indeed, evolution can be thought of as a model of change by replication, as opposed to a model of inherent change. Replication also occurs in cultural transmission, including language change (Mesoudi et al., 2004; Pagel, 2009). In both biological and cultural evolution, there is debate over what is the replicator, that is, what it is that replicates. In neo-Darwinian evolutionary theory, the paradigm case of the replicator is the gene, and we will use this example for initial illustration.

The fundamental properties of the replication process, most of which are explicated by Darwin, can be grouped into two categories (Dawkins, 1976). The first category has to do with how replicators form lineages. A replicated unit can itself be replicated; the replication process can proceed indefinitely. And some replicators must survive long enough to be replicated themselves (these properties are also called longevity and fecundity). The second category has to do with inheritance, namely what makes the replication process nonrandom. Replicated units possess much of the structure of the original unit. The replication process is mostly faithful. But replication can produce heritable variation: that is, the replication process introduces variation, and that variation is cumulative over generations of replicators.

Among theorists of cultural evolution, three sorts of entities have been proposed as replicators: artifacts, behaviors, and concepts, that is, mental entities. An issue with all of these replicator types is that their replication must be indirect. Artifacts and behaviors are reproduced by human agents, who use their cultural knowledge (i.e., mental conceptual structures) to replicate them. For concepts to be replicated from one person to another ('learning'), they must be publicly displayed in terms of human actions (behavior) or products (artifacts). In addition, concepts are not directly observable and there is evidence that the neural structures and patterns of activation for the same concept may differ from person to person.

In language change, the debate has been traditionally framed in terms of whether language change takes place through imperfect learning by children, or via language use. In evolutionary terms, this is a debate over whether the replicator is a grammar (that is, a speaker's knowledge about his or her language) or linguistic structures in utterances (such structures are replicated every time we speak). Both theories have been debated since the emergence of historical linguistics in the nineteenth century, and the debate continues.

There is considerable empirical evidence that imperfect learning by children cannot be the source of language change (Croft, 2000). Children's errors in acquisition (that is, their linguistic innovations) do not match the processes observed in language change. Children are very good at learning the language spoken around them even though they are not provided with direct negative evidence about the structure of their language (specialists in child language acquisition call this the 'no negative evidence problem'). Finally, children's language is not emulated by other social groups in language change; instead, children expend their effort in emulating other social groups, in particular their older peers when they become adolescents.

By contrast, the sort of variation that is found in the phonetic realization of sounds, and in the verbalization of experience into words and constructions, does match observed

language changes (Croft, 2010). An important element of the usage-based model of language change is that knowledge of language includes knowledge of language variation, and that language variation is pervasive in language. Hence language change is actually a process by which change occurs in the distribution of linguistic variants across phonetic space (for sounds) or conceptual space (for words or constructions). While adults are not as flexible as children in changing their patterns of language use, there is some flexibility, which is greater for some linguistic units (e.g., new words) and less for others (accent); and adults vary in their receptiveness to novel linguistic variants.

Cultural replicators have been called memes (Dawkins, 1976). However, memetics has combined the basic properties of replicators and replication with a 'selfish gene/selfish meme' theory of selection. Selection represents the other fundamental principle of Darwinian evolutionary theory. Selection is a process by which some replicators are successfully propagated in a population while other replicators go extinct (in the extreme case). Selection is a separate process from replication. Most evolutionary biologists recognize that evolution is a two-step process: the generation of variation via replication and selection of some variants over others (also called differential replication).

In the 'selfish gene/meme' approach, the replicator (gene or meme) functions as both the locus of replication and of selection. In biology, the organism is merely a vehicle to facilitate the gene's successful replication, and by analogy, in cultural change, a human agent is merely a means for concepts to differentially replicate themselves. This approach has been controversial in both biology and theories of cultural evolution including language change (but see Ritt, 2004).

Most biologists consider the selfish gene theory to miss the important roles that entities other than the gene play in biological evolution. Analogously, the selfish meme theory misses the important roles that entities other than the meme, in particular human agents, play in cultural evolution. Another generalized theory of evolution, the General Analysis of Selection, provides a richer, though still highly abstract, theory of evolutionary processes (Hull, 1988). The General Analysis of Selection includes the replication process, but analyzes selection as a process of environmental interaction that causes differential replication to take place. Environmental interaction defines two more roles, the environment and the interactor. In the neo-Darwinian theory of biological evolution, the canonical interactor is the organism: an organism interacts with its environment, and natural selection brings about the differential replication of its genes depending on the survival and reproductive success or failure of the organism.

The General Analysis of Selection can also be applied to language (Croft, 2000). The interactor is the human agent, namely the speaker. The speaker's environment includes the experience being communicated, the speakers with whom he or she converses, and the social structures that bind those speakers together in a speech community. In that context of language use, speakers make choices as to which linguistic variants to replicate. The variants that get replicated more frequently are propagated through a speech community, and in the end a historical linguist observes that a language change has taken place.

The General Analysis of Selection provides a framework for an evolutionary model of the processes that have been observed in sociolinguistics. Sociolinguistics observes variation in language use in a speech community. (Sociolinguists generally do not consider the origins of that variation; it has been argued to result from language production, as discussed earlier.) In particular, some of the variation in language use is socially structured: that is, it correlates with social parameters such as gender, age, and socioeconomic status. The association of variants with particular social parameters appears to drive the propagation of certain variants in the speech community, that is, selection of those variants by the speakers in the community.

Another element of a generalized evolutionary theory that plays a central role in cultural evolution and language change is population thinking. The term 'population thinking' refers to the definition of species that emerged by the neo-Darwinian synthesis in the early twentieth century. The population definition replaces the essentialist definition of species that preceded evolutionary theory. In the essentialist approach to species, a species is defined as an ahistorical type with certain essential properties. The essentialist approach is problematic for actual biological species for several reasons. There is a high degree of variation among individuals in a single species; 'essential' traits may be lacking in many individuals. Conversely, two species may overlap substantially in their traits, so 'essential' traits would not distinguish species (and in fact, there are many disputes about how many species there are in particular genera). Finally, the 'essential' traits of a species change over time as species evolve.

The population approach avoids all of these problems. In the population approach, a species is defined not by an essential trait of individuals, but an interactional trait among the members, namely interbreeding (in sexual organisms) and its converse, reproductive isolation between populations. This interactional trait is also the way in which populations form lineages: interbreeding leads to reproduction and lack of interbreeding eventually splits a population. Recently, different definitions of species have been proposed. However, these definitions appear to be the consequence of the fact that populations diverge slowly when interbreeding stops between the populations, and the recent species definitions differ as to what point diverging populations are said to constitute distinct species.

Languages suffer from the same problems with essentialist definitions as biological species. Languages are internally highly variable, so that one cannot provide an 'essential' set of words and/or grammatical rules that would define a language. Two languages may share large amounts of lexicon and grammar, and there are disputes in many cases as to whether there are two languages or two dialects of a single language. Finally, languages change, so 'essential' features of languages may change.

The general solution is to offer a social definition of a language, since a structural (i.e., essentialist) definition is unsatisfactory. More precisely, a population definition of a speech community will avoid the problems of defining a language, since a language is produced by members of the speech community (Croft, 2000; Mufwene, 2001). A population definition of a speech community is a set of speakers that converse with each other. Since what the members of the speech community produce in conversation is the language of that community, it accommodates

variation in the language. When a speech community splits, the languages they speak gradually diverge as the speakers of the two communities stop interacting. At first, the languages are structurally quite similar, but over time they will come to differ; linguists may disagree about the point at which they would say there are now two distinct languages.

Language populations, that is, speech communities, are never completely communicatively isolated from their neighbors. The result is language contact. Although this is sometimes held up as a disanalogy between language change and biological evolution, there is in fact much hybridization in the biological world outside of animals, and many instances of introgression that leads to the transfer of genes from one population to another through incomplete reproductive isolation. Language contact leads to sometimes large-scale transfer of linguistic structures or features from one speech community to another, particularly in the creation of new speech communities through the immigration of multiple populations in colonial situations (new dialect formation and creole formation; Trudgill, 2004; Mufwene, 2001, 2008). As in the case of the selection of certain linguistic variants in a single speech community, selection of linguistic variants from the members of different speech communities that come together in a colonial situation is influenced by social factors that operate in the circumstances of the colonization (the dominance of some groups and enslavement of others, the demographic proportions of speakers, and so on).

The employment of an evolutionary framework for understanding language change allows for the development of mathematical models of mechanisms and processes of language change. Such models are agent-based models, in which entities that represent speakers (as human agents) interact with each other and produce linguistic structures, constrained by a range of competing factors. The process of replicating these linguistic structures feeds back into future linguistic behavior of the agents in a cumulative fashion, leading to evolutionary change in the language produced by the agents/speakers. In other words, these mathematical models represent language as a complex adaptive system (Ellis and Larsen-Freeman, 2009).

The relationship between evolution and language is sufficiently parallel that both can be subsumed under a generalized model of evolutionary processes, and specific mathematical models can be applied to both. Although many linguists, particularly historical linguists, have observed the parallels between evolution and language, a reassessment of the nature of theories and models of language based on an evolutionary perspective is a relatively recent phenomenon in linguistics. The level of impact of evolutionary thinking on linguistic theorizing remains to be seen.

Evolution and Language: Phylogenetic Analyses

Simon Greenhill, Australian National University, Canberra, ACT, Australia

Abstract

Language phylogenies are a potentially powerful way to answer questions about how languages and cultures evolve. Recently, phylogenetic methods have been applied to a range of questions about the evolution of human languages and cultures. This article reviews the historical background of these approaches and provides a detailed methodological overview. Three different applications of phylogenetic methods are discussed: how language phylogenies can be used to test population dispersal hypotheses, to investigate processes in language evolution, and to infer patterns in cultural evolution. The article discusses briefly some controversies over the use of these methods before closing with some future prospects.

Language as the Archives of History

There are more than 7000 languages spoken in the world today (Lewis, 2009). These languages can be divided into more than 200 major language families, each containing related languages that have diversified from a common ancestor. For example, the ~12 000 languages of the Austronesian language family originated with a common ancestor – known as Proto-Austronesian – around 5500 years ago (Blust, 1999; Pawley, 2002). The relationships between these languages trace how they and their speakers diverged and expanded over time. Therefore, a family tree or *phylogeny* of these languages holds many clues for investigating the past.

Recently, there has been a series of studies that have applied computational phylogenetic methods from evolutionary biology to languages. These *language phylogenies* have been used to test some prominent and controversial hypotheses in linguistics and anthropology. One subset of studies has tested population dispersal hypotheses including the spread of Indo-European speakers through Europe (Bouckaert et al., 2012; Gray and Atkinson, 2003), the peopling of the Pacific by Austronesian language speakers (Gray et al., 2009), and population expansions in sub-Saharan Africa (Holden, 2002), the Middle East (Kitchen et al., 2009), Japan (Lee and Hasegawa, 2011), and Australia (Bowern, 2010, 2012).

Another set of studies has used language phylogenies to quantify processes in language evolution. These studies have searched for deep linkages between the languages of Melanesia (Dunn et al., 2005), investigated the causes of variation in rates of language evolution (Atkinson et al., 2008; Greenhill et al., 2010; Pagel et al., 2007), and tested how language structures coevolve (Dunn et al., 2011).

Yet other studies have used language phylogenies as a backbone for testing hypotheses about human cultural evolution. These studies include inferring kinship systems (Jordan, 2011; Jordan et al., 2009), how farming and patriliny coevolved (Holden and Mace, 2005), and how political complexity arose in the Pacific (Currie et al., 2010).

Historical Background

Evolutionary biology and historical linguistics share many curious parallels (see Atkinson and Gray, 2005). To understand their respective study material, both fields need to make historical inferences: When did a species or language arise? Where did it come from and what relationships does it have with others? How has the species or language changed over time?

The tree of life is a commonly used concept in evolutionary biology to represent these historical relationships. Since at least the time of Lamarck (1809), trees have been used to describe the history of species and their relationships. It was Darwin, however, who planted this tree at the center of evolutionary theory: the only figure in the *Origin of Species* (Darwin, 1859) is the tree of life.

Darwin was late. Linguists had already been using trees to describe language relationships for some time (Schlegel, 1808; Schleicher, 1863). Trees quickly became commonplace in both evolutionary biology and historical linguistics as descriptions of history. Both fields started to develop quantitative methods for building family trees and making inferences from them. Historical linguistics invented *lexicostatistics* and *glottochronology*. Evolutionary biology started to develop *numerical taxonomy* and *phylogenetics*. Both fields encountered teething problems with these methods. However, here the curious parallels between evolutionary biology and historical linguistics begin to break down. Historical linguistics largely rejected quantitative methods while evolutionary biology developed and improved the methods into a large set of tools known as *phylogenetic methods*.

Historical Linguistics and the Rise and Fall of Lexicostatistics

In a series of papers, Morris Swadesh proposed that the best way to infer language relationships was to count the number of shared similarities on a word list of basic vocabulary. These similarities were not just 'look-alikes' but were *cognate* words. Cognates are words in two languages that have descended from a common ancestor. For example, the words for 'taboo' in Maori (*tapu*), Tahitian (*tapu*), and Hawaiian (*kapu*) are cognates. The words for 'three' are also cognate: *toru* in Tahitian and Maori and *kolu* in Hawaiian. Historical linguistics identifies these cognates by finding systematic sound correspondences between multiple words. Here, *k* in Hawaiian systematically corresponds with *t* in Tahitian and Maori in many words. These systematic sound correspondences diagnose specific phonological innovations that occurred during those languages'

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81035-1

evolutionary history. In this case, the ancestor of these languages – Proto-Polynesian – probably had forms like *tolu* and *tapu* and changed all *t* to *k* after it diverged from Proto-Polynesian (Greenhill and Clark, 2011).

Swadesh argued that the number of cognates shared on a word list measured similarity. The word list Swadesh used contained a varying number of items of *basic vocabulary* that were selected as universal and easily identifiable concepts that could be matched across languages. These items included words for body parts (e.g., hand, head), personal pronouns (e.g., I, we), colors (e.g., black, green), lower numerals, and highly recurrent verbs (e.g., to walk, to swim).

According to Swadesh, the more cognates two languages shared in their basic vocabulary, the more closely related they were. Successively grouping the languages with the highest similarity would therefore build a family tree of those languages. This approach became known as *lexicostatistics*.

Swadesh extended lexicostatistics into *glottochronology* – a system for inferring the ages of language divergences. Glottochronology assumed that languages lost their shared cognates at a constant rate over time. Given a count of cognate similarities between two languages and a rate at which cognates were lost, one could infer divergence times with the following equation:

$$t = \frac{\log C}{2 \log r}$$

where C is the number of shared cognates and t is the amount of time. The value for r was the *retention rate*, i.e., the rate at which cognates were retained. Swadesh initially chose a value of 85% every 1000 years for r, based on the differences documented between Old and Modern English (Swadesh, 1950). A later study by Lees (1953) refined this rate to 81% every 1000 years based on a 200-item word list from 13 historically attested languages. Therefore, according to glottochronology, if two languages shared 81% of their basic vocabulary after 1000 years, they would share 66% after 2000 years and 43% after 3000 years, and so forth.

Swadesh (1950) first applied this method to the Salishan languages spoken in the Pacific Northwest. Lexicostatistics and glottochronology were rapidly applied to languages around the world (e.g., Elbert, 1953; Hymes, 1960; Lees, 1953; Swadesh, 1955, 1950). The results were of great interest and discussed by eminent anthropologists (e.g., Kroeber, 1955) and cited as revolutionizing prehistory (e.g., Murdock, 1964).

However, this popularity did not last due to some serious methodological issues. The supposedly universal word lists were not applicable to all languages ('ice' and 'snow,' e.g., are not common in the Pacific), nor did the simple pairwise count of similarity distinguish between items that were innovated in a lineage or were simply retained from some common ancestor. But the key criticism was rate variation. When rates of change varied between languages, there was a high risk that both the subgroups and the dates were wrong. The most damaging study by Bergsland and Vogt (1962) pointed out that Old Norse and Icelandic diverged around 1000 years ago. Glottochronology estimated their divergence at less than 200 years. In fact, rather than a very tightly constrained retention rate of around 81% cognate loss every 1000 years, Bergsland and Vogt found that the rate varied by around 15–20%.

While some practitioners of lexicostatistics worked to improve the methods (e.g., Embleton, 1981; Sankoff, 1973), they had lost the war. By this time, historical linguistics had largely rejected quantitative methods and lexicostatistics became a textbook example of how not to do linguistics. This rejection has been so complete that even 50 years later linguists are still cautioned that 'linguists do not do dates' (McMahon and McMahon, 2006).

Evolutionary Biology and the Phylogenetic Revolution

Meanwhile, in evolutionary biology, taxonomists had developed tools for building and dating trees that mirrored those found in lexicostatistics. A method known as unweighted pair-group method using arithmetic averages (Sokal and Michener, 1958), or UPGMA, built phylogenetic trees from pairwise genetic similarity just as lexicostatistics did with linguistic similarity. UPGMA and similar methods were extended to estimate divergence times using the assumption of a 'molecular clock' (Zuckerkandl and Pauling, 1965). Kimura (1968), for example, estimated the average time for one base pair change in the genome to be 1.8 years.

Just like linguists, biologists were quick to notice that there were major problems with this method. As with lexicostatistics, these 'numerical taxonomic' methods were undone by variation in rates of genetic change. Variation in rates could lead to markedly incorrect estimates of both the relationships between species (Felsenstein, 1978) and the estimated divergence times (Kirsch, 1969).

Unlike linguists, however, biologists actively sought to improve their methods to handle these problems. First, the problems with methods that calculated pairwise similarity (like UPGMA or lexicostatistics) led to the development of methods that built trees from the raw data itself rather than a summary statistic (Cavalli-Sforza and Edwards, 1967). Second, methods were developed to explicitly account for rate variation in molecular evolution (e.g., Penny et al., 2001; Yang, 1993). Third, the dating of divergence events has become much more robust with a range of new methods that incorporate known historical information and that 'smooth' or 'relax the clock' to account for variation in rates of change over time (e.g., Drummond et al., 2006; Sanderson, 1997). Finally, there has been substantial theoretical development in 'tree thinking' (O'Hara, 1997, 1988) as biologists have realized that trees are not merely diagrams of evolution, but provide ways of testing hypotheses about evolving systems.

Modern Phylogenetics

These methodological and theoretical advances have led to the development of a major field of *phylogenetics* (see also Comparative Method in Evolutionary Studies). The birth of this field was not easy or quiet – debates about phylogenetics were notoriously vicious (Hull, 1988). However, today these phylogenetic methods provide some of the most powerful ways of testing evolutionary hypotheses and have come to dominate evolutionary biology (Huelsenbeck et al., 2001). Phylogenies have become so important in biology that

around 15 new trees are published every day (Rokas, 2006), and being able to read phylogenies is seen as important to biologists as reading a map is to geographers (Gregory, 2008).

The ubiquity of phylogenetic methods in biology have meant that they have cross-fertilized neighboring disciplines including cultural evolution (e.g., Gray et al., 2007), the evolution of manuscripts (e.g., Howe et al., 2001), and musicology (e.g., Rzeszutek et al., 2011). One of the most successful cross-fertilizations has been the wave of studies applying phylogenetic methods to languages.

Bayesian Phylogenetic Methods

Currently, the approach of choice for language phylogenies is a set of tools known as Bayesian phylogenetic methods (Huelsenbeck et al., 2001). Bayesian phylogenetic methods treat the data as fixed observations and aim to fit a model of language change to the data, estimate the model parameters from these data, and use this to infer the best fitting trees using a likelihood framework. There are therefore four major components of a phylogenetic analysis: the data, the model, calculating the likelihood, and the tree search.

Data

The first component of the analysis are the data. Phylogenetic analyses need large amounts of good-quality data to resolve language subgroupings. Cognates from basic vocabulary are often used because they are relatively stable over time and resistant to borrowing (Greenhill et al., 2008). More importantly, however, there are large-scale databases of basic vocabulary and cognate data available for analysis (e.g., Greenhill et al., 2008; Greenhill and Clark, 2011). These data are usually encoded as a binary matrix showing presence or absence in each language (see Table 1).

Cognate data are not the only type of data that can be used – studies have also used information about language structures and typology (Dunn et al., 2005; Greenhill et al., 2010). The only restriction on the data is that there needs to be some way of modeling how they evolve over time.

Model

The next component is a model of how these data could change on a tree. Cognates can either be gained or lost. A cognate gain would occur when a language changes to have the same cognate set for an item such as when a new cognate is 'born' in an ancestral protolanguage. A loss of a cognate would occur when a language changes out of a cognate group when a new lexical innovation arises.

A very simple model of cognate change might allow cognates to be gained or lost at the same rate. This rate is known as a *parameter* of the model. Each model parameter can either be fixed to a known value or estimated from the data. This model with one parameter is quite unrealistic – perhaps cognates are gained at a different rate to being lost. We might expect that it is much harder to gain a new cognate set than it is to lose one. The model could therefore specify two rate parameters – one of cognate gains and one of cognate losses. Yet more complex models would allow the rates of gains and losses to vary over time, e.g., a *covarion* model (Penny et al., 2001), or to enforce the idea that losses are much more numerous than gains by forcing cognates to only arise once, e.g., a *stochastic dollo* model (Alekseyenko et al., 2008; Nicholls and Gray, 2006). All these simple models are often used in reconstructing language phylogenies.

More complex models with more parameters can better model how languages change. If the model is too simple – i.e., *underparameterized* – then one runs the risk of missing important aspects of language change and getting the wrong answer. However, as the model becomes more complex, substantially more data are needed to estimate the values of the parameters effectively (Burnham and Anderson, 1998). If the model is too complex for the available data, then it is *overparameterized* and estimates of the parameter values are likely to be incorrect. There is therefore a balance between an adequately complex model and the amount of data. In practice, most studies fit a range of models to the data and use a model comparison – such as a Bayes Factor (Kass and Raftery, 1995) – to choose the best fitting model.

Given a model of cognate change and some data, one can calculate the fit of those data onto any given tree. To do this, a numeric value called the *likelihood* is calculated, which is simply the probability of the data given, the tree, and the model. The likelihood is the sum of all possible state assignments to the internal nodes. As such it mimics the process of subgrouping languages or species based on shared innovations and not common retained traits. Because the likelihood is the outcome of repeatedly multiplying probabilities, it becomes very small and it is therefore common to report *log likelihood* scores instead.

Table 1 Cognates in some items of basic vocabulary in five Central Pacific languages

	Taboo	*Blood*	*To suck*	*Taboo*	*Blood*	*To suck*[3]	*To suck*[4]
Fijian	tabu[1]	drā	sucu-ma	1	0	0	0
Maori	tapu[1]	toto[2]	ngote[3]	1	1	1	0
Tahitian	tapu[1]	toto[2]	'ote[3]	1	1	1	0
Marquesan	tapu[1]	toto[2]	omo[4]	1	1	0	1
Hawaiian	kapu[1]	koko[2]	omo[4]	1	1	0	1

The left side of the table shows three items of basic vocabulary. Different cognate sets are marked with superscript numerals. Note that 'to suck' has two cognate sets. The right side of the table shows the binary presence/absence coding of these cognate sets. Noncognate items (Fijian 'drā' and 'sucu-ma') are ignored.

Finding the Most Probable Trees

The likelihood gives a way to score different trees according to how well they explain the data under the chosen model of cognate change. However, finding the best trees is hard – there are incredibly many possible permutations. Once there are more than 50 languages in the analysis, there are more possible trees than atoms in the universe.

To find the highly probable trees from this space of possible trees, a Bayesian inferential approach that combines the likelihood with prior knowledge of trees and parameter values is used to give a *posterior probability* distribution of trees. The posterior distribution contains the trees that fit the data well

(i.e., have high likelihoods) given the data, the model of cognate change, and the *priors*. Priors are the initial starting values used for the model parameters. Often priors are 'flat,' considering all possible values as equally probable, but if there is strong external evidence for what these parameters might be, then this can be explicitly taken into account (Huelsenbeck et al., 2001).

Calculating the posterior distribution is hard, requiring the integration of all model parameters over all possible branch-length combinations on every tree. However, a method known as *Markov-Chain Monte Carlo* (MCMC) can sample trees from the posterior probability distribution. To start with, MCMC randomly generates a tree. The initial values for each parameter are sampled from the prior distributions. This original tree is then randomly permuted in some way – by moving a branch on the tree or by modifying one of the model parameters. This permutation gives a new tree that is different from the previous tree by only one change. By calculating the likelihood on this new tree, it can be compared to the old tree to see if it explains the data better. If the new tree fits the data better, then one keeps this tree. If the new tree is worse, then one reverts to the old tree.

This process is repeated many millions of times, sampling the tree and the model parameters at each generation. To start with, the initial trees are poor estimates of the real tree and have incorrect parameter values – this is known as the *burn-in* period. However, because the method preferentially selects the better tree at each generation, the trees and parameters converge toward good estimates of their real values. After running the chain for many generations, the analysis essentially samples the best trees from the space of possible trees to give the posterior probability distribution.

Applications of Language Phylogenies

Testing Population Dispersal Hypotheses

A major use of language phylogenies has been to test hypotheses about how human populations expanded and dispersed across the globe (see also Cultural Evolution: Phylogeny versus Reticulation). One of the greatest human dispersals was the settlement of the Pacific. During the Holocene, a new culture arose in the Pacific and spread through the region from Taiwan, into Island Southeast Asia, on to Oceania, eventually reaching as far afield as Madagascar, Hawaii, Rapanui (Easter Island), and New Zealand. This journey was made all the more impressive by being undertaken without the help of modern sailing equipment. As these people settled this region, their languages diversified into the vast Austronesian language family. These Austronesian languages now comprise one of the largest language families in the world containing between 1000 and 1200 languages (Blust, 2009).

There are two competing theories about where these people came from and how they spread through the Pacific (Gray et al., 2009). The first theory, the *pulse-pause* scenario, proposes that the Austronesians originated in Taiwan around 5500 years ago and expanded through the Pacific in a series of expansion pulses and settlement pauses (Blust, 1999; Diamond and Bellwood, 2003; Pawley, 2002). According to this scenario, after the initial settlement of Taiwan there was a settlement pause of around 1000 years followed by a major expansion pulse into the Philippines, through Island Southeast Asia, along the coast of New Guinea, before reaching Tonga, Samoa, and Fiji around 2800–3000 years ago (Burley et al., 2012). Here, a second settlement pause occurred, coinciding with the development of the pre-Polynesian society (Kirch and Green, 2001). Around 1000 years ago, a second expansion pulse occurred as these peoples – now Polynesian – expanded into Eastern Polynesia, eventually reaching Hawaii, New Zealand, and Rapanui around 800 years ago (Wilmshurst et al., 2011).

In contrast, the second theory of Pacific settlement, the *slow boat* scenario, proposes that the Austronesians originated in Wallacea – the area around Sulawesi and the Moluccas (Oppenheimer and Richards, 2001). The slow boat scenario claims that the Austronesians expanded out of Wallacea around 13 000–15 000 years ago following rises in sea level after the submerging of the Sunda shelf at the end of the last ice age. According to this scenario, the Austronesians expanded in two prongs – the first headed north through the Philippines and into Taiwan, while the second traveled east along the New Guinea coast into Polynesia.

Gray et al. (2009) used language phylogenies to test between these two scenarios. Their dataset was more than 34 000 cognate sets from 400 Austronesian languages (Greenhill et al., 2008). The results from Gray et al. (2009) showed overwhelming support for the pulse-pause scenario. First, the Austronesian trees were rooted in the Formosan languages of Taiwan – not in Wallacea – and showed a single chainlike pattern rather than a two-pronged expansion.

Second, the two scenarios propose quite different timings for the Austronesian expansion. The pulse-pause predicts an origin around 5500 years while the slow boat predicts an age between 13 000 and 15 000 years. To test this prediction, Gray et al. (2009) used a nonparametric rate–smoothing approach to convert the branches on the trees (here measuring amount of lexical change) into time. This method smooths the observed rates of change across the trees in the posterior distribution while accounting for historical calibrations (Sanderson, 1997).

The historical calibrations were based on known historical information about parts of the tree, e.g., the development of the large Proto-Oceanic subgroup 3200–3600 years ago (Lynch et al., 2002), the settlement of the Reefs and Santa Cruz islands between 3000 and 3150 years ago (Green et al., 2008), and the historical attestation of the Chamic Subgroup between 1800 and 2500 years ago (Thurgood, 1999). Dating the trees in the posterior distribution showed an average age of 5230 years (95% highest posterior density interval = 4750–5800 years ago). This finding again supports the pulse-pause scenario instead of the slow boat.

Strikingly, the trees revealed that the pattern of expansion pulses and pauses visible in the trees matched those predicted by the pulse-pause scenario. If language diversification were linked to the population expansions, then expansion pulses will leave little time for linguistic changes to accumulate. In pulse regions, the trees will have small, short branches. In contrast, the settlement pauses will show long branches due to the increased amount of lexical changes accumulated. The Austronesian trees showed precisely this pattern – long branches matching the settlement pauses and short branches

matching the expansion pulses. In sum, the study by Gray et al. (2009) shows the great promise of phylogenetic methods for testing population dispersal hypotheses in terms of timing, pattern, and sequence.

Quantifying Processes of Language Change

Understanding the tempo of language change is critical for many questions in historical linguistics. What aspects of languages are stable over time and what types are rapidly changing? This information is important for resolving language relationships – if we want to identify deep language relationships, then slowly changing features should be our data of choice. On the other hand, more rapidly changing features can provide finer-grained resolution at shorter time scales.

A series of phylogenetic studies has investigated the tempo of change in lexical items. Pagel and Meade (2006) constructed trees of 87 Indo-European languages using Bayesian phylogenetic methods. They then calculated the instantaneous rates of change (i.e., the rate at any point on the phylogeny) for items of basic vocabulary using a statistical model of word evolution. This rate was converted into a *half-life*, i.e., the amount of time needed for a word to lose 50% of its cognates. The average half-life for each word in both families was 2343 years and a median of 1449 years. The slowest words in the Indo-European languages were 'two,' 'three,' 'five,' and 'who' with an estimated half-life of 19 600 years.

What might cause these variations in rates of change? One factor thought to influence the rate of change is frequency of use. Pagel et al. (2007) extended their previous study by comparing the rates of change in lexical items to the frequency those items were used in four large corpora of English, Spanish, Russian, and Greek languages. The results show that the rate of lexical change in the lexicon is predicted by the frequency at which words are used in modern-day languages. That is, the more a word is used in speech, the less likely it is to change. This frequency of use effect is strong, explaining about 50% of the variation in the rates of change in these items of lexicon.

Using phylogenetic methods to investigate rate variation also allows us to explore broader questions about the patterns of change. A long-standing debate in linguistics concerns how far back one can trace prehistory. The accepted rule of thumb suggests that the tempo of language change is so fast that any historical signal is lost after 10 000 years (Ringe, 1995). However, if there are features that are more stable, one might be able to trace language relationships at far deeper levels (Gray, 2005). Some authors have argued that certain structural features, like word order or pronoun systems, are very stable over time and can identify language relationships dating back tens of thousands of years (Nichols, 1992).

To test the hypothesis about structural features, Greenhill et al. (2010) used a phylogenetic approach to infer the rates of change in Austronesian and Indo-European languages for 200 items of basic vocabulary and 138 structural/typological features. The results showed that, on average, the lexical items changed slightly faster than the structural features in the Austronesian languages but there was no significant difference in the Indo-European languages. More importantly, many of the features proposed to be highly stable were not – showing marked variation between the two language families. For example, the subset of structural features related to nominal syntax has some of the highest rates of change in Austronesian, but is among the slowest in Indo-European. There was no significant relationship in rates of change between Austronesian and Indo-European. These results showed that structural features were not changing significantly slower than the lexicon and the rates were not consistent between families. This study highlights the problems with broad assumptions of stability between different languages and suggests that phylogenetic methods might provide a better way of moving these debates forward by directly testing these implicit assumptions.

Investigating Cultural Evolution

Language phylogenies provide a way of testing hypotheses about cultural evolution (see Cultural Evolution: Overview). A major problem for statistical tests on cultures is that cultures share similarity due to descent and are therefore not statistically independent. This is known as Galton's problem (Naroll, 1961). One of the great benefits of phylogenies is that they directly estimate the similarity due to descent, allowing this to be controlled for. This benefit has led to the development of a series of *phylogenetic comparative methods* for testing comparative hypotheses (Felsenstein, 1985). Unfortunately, large-scale cross-cultural databases are lacking (Greenhill et al., 2008). However, since languages trace the history of cultures well they can work as a proxy for culture history. When coupled with phylogenetic comparative methods they provide a powerful tool for investigating cultural evolution (Mace and Pagel, 1994).

For example, one study used the Austronesian language phylogenies described above to test how political complexity evolved (Currie et al., 2010). Anthropologists have classified societies into different stages of political complexity. These stages range from small *acephalous* societies without any permanent leadership, to *simple chiefdoms* with one level of leadership beyond the local community, to *complex chiefdoms* with two levels of leadership, and then to *states* with more than two levels. There has been much debate about how these differences in political complexity arose. Do societies move through these levels to increase in complexity (e.g., band to tribe to chiefdom to state)? Does this sequence always have to be followed, or can societies change between these levels freely?

To investigate these questions Currie et al. (2010) used the Austronesian language phylogenies discussed earlier (Gray et al., 2009). They first collected information about political complexity for the Austronesian societies speaking the languages used in the language trees. These data classified each society into one of four stages (acephalous, simple chiefdom, complex chiefdom, and state). The society stages were then mapped onto the Austronesian phylogenies from Gray et al. (2009). Currie et al. then fitted different models of how political complexity could evolve onto these trees and data. For example, one model specified that only sequential increases in complexity were possible. Another model specified that only sequential increases and decreases were

possible. Yet other models allowed major jumps or catastrophic declines in complexity. Calculating the fit of these models onto the trees and the data showed which model explained these data the best.

Currie et al.'s results showed that the best fitting model only allowed sequential increases and decreases in complexity. That is, the political complexity in these Austronesian societies tended to increase or decrease only in small steps between stages. There were no big jumps in complexity (e.g., from acephalous societies to states). The next best fitting model was one that allowed catastrophic decreases suggesting that while major increases in complexity might not happen, collapses do.

Controversies

Language phylogenies have often been controversial. Following the rejection of lexicostatistics, historical linguistics has had a 'tradition of hostility toward probabilistic modelling' (Sankoff, 1973, p. 96). Phylogenetic methods are often criticized for simply being 'lexicostatistics redux,' with all the fatal flaws inherent within lexicostatistics. However, phylogenetics developed in response to many of the same problems faced by lexicostatistics and has moved far beyond lexicostatistics in power and robustness (Greenhill and Gray, 2009).

The most substantive criticism of language phylogenies is that languages do not necessarily evolve like species do (Bateman et al., 1990). The main component of this argument is that languages can borrow cognates, typological features, or grammatical structures from other languages. English, for example, has borrowed around 60% of its lexicon from French and Latin (Embleton, 1986). The critics argue that high levels of borrowing cause phylogenetic methods to give inaccurate or invalid results.

This criticism has lead to a highly polarized debate between those who think that trees can represent linguistic and cultural evolution well and those who think that phylogenetic methods should be rejected (see Greenhill et al., 2009). The truth is somewhere in between. First of all, an important component of phylogenetic analysis is choice of data. The data of choice for most language phylogenies to date – basic vocabulary – are resistant to being borrowed. While English has borrowed up to 60% of its total lexicon from French and Latin, only about 6% of its basic vocabulary is from these languages (Embleton, 1986). Choosing the right data is half the battle.

Borrowing is not an all-or-nothing prospect – the key question is what levels of borrowing are problematic. To answer this question, Greenhill et al. (2009) simulated borrowing of words on language trees and then attempted to reconstruct their histories. The results showed that Bayesian phylogenetic methods were robust to even quite high levels of borrowing – 15–20% of the basic vocabulary every 1000 years. Therefore, we would expect these methods to work quite well even when borrowing is reasonably common.

When borrowing is substantial, alternative approaches do exist. The languages of Polynesia and Vanuatu, for example, are notorious for high levels of borrowing and complex dialect chains. In biology, phylogenetic network methods like NeighborNet or Split Decomposition (e.g., Huson and Bryant, 2006) have been developed to handle cases where there are multiple histories – such as when plants hybridize or when bacteria exchange genetic material between different species. In linguistics, these networks have been used to visualize complex and conflicting patterns of descent for some time (e.g., Bryant et al., 2005; Greenhill et al., 2010). Until now, phylogenetic networks were primarily visualization tools. Recently, however, these methods have been applied to languages to estimate the amount of lexical borrowing in Indo-European languages (Nelson-Sathi et al., 2011), and to quantify the amount of conflicting signal in various linguistic and cultural datasets (Gray et al., 2010). Perhaps the best way to analyze the complex descent patterns found in places like Vanuatu and Polynesia is to use these recently developed phylogenetic network methods rather than phylogenetic trees (Gray et al., 2010). These methods are still in their infancy but show great promise for helping investigate complex histories.

Conclusions and Future Prospects

To date, language phylogenetic work has been largely driven from outside historical linguistics but shows great potential for complementing the historical linguistic tool set. The future development of this field hinges on moving beyond the wholesale importation of methods from evolutionary biology. Major advances will come from *transforming* these methods to be more appropriate for languages, for example, through better models of sound change (e.g., Bouchard-Côté et al., 2009) or better ways for handling complex borrowing and diversification patterns (Gray et al., 2010).

The three applications presented above hint at the promise that a phylogenetic approach to languages has. In terms of testing population dispersal hypotheses, these methods can help us locate language families – and cultures – in both space and time. With well-dated trees of languages and cultures, one will be able to gain a much better understanding of prehistory. In terms of the processes in language evolution, phylogenetic methods can infer and quantify the large-scale broad patterns that have shaped the languages spoken today. As for investigating cultural evolution, language phylogenies give a robust set of tools for making inferences about how human societies have evolved. When combined with good linguistic and cultural data, language phylogenies provide a very powerful set of tools for answering questions about human prehistory and how languages evolve. These methods raise the possibility of an exciting new field of computational historical linguistics that can bring linguistics into the forefront of the human sciences.

Evolution: Diffusion of Innovations

Everett M Rogers,[†] University of New Mexico, Albuquerque, NM, USA

This article is reproduced from the previous edition, volume 7, pp. 4982–4986, © 2001, Elsevier Ltd.

Abstract

This article discusses the model of the diffusion of innovations and describes this model's key variables. Diffusion is the process by which an innovation is communicated through certain channels over time among the members of a social system. An innovation is an idea, practice, or object that is perceived as new by an individual or other unit of adoption.

This article discusses the model of the diffusion of innovations and describe this model's key variables. First, however, a brief history of diffusion research is presented. The paradigm for diffusion research can be traced to the rural sociology research tradition, which began in the 1940s. Rural sociology is a subfield of sociology that focuses on the social problems of rural life. One rural sociology study in particular influenced the methodology, theoretical framework, and interpretations of later students in the rural sociology tradition, and in other diffusion research traditions. Ryan and Gross (1943) investigated the diffusion of hybrid seed corn among Iowa farmers. Hybrid seed, the result of agricultural research, was made available to Iowa farmers in 1928. The hybrid vigor of the new seed increased corn yields on Iowa farms, hybrid corn varieties withstood drought more effectively than the open-pollinated seed they replaced, and hybrid corn was better suited to harvesting by mechanical corn pickers. By 1941, about 13 years after its first release, the innovation was adopted by almost 100% of Iowa farmers. Ryan and Gross studied the relatively rapid diffusion of hybrid corn in order to obtain lessons learned that might be applied to the diffusion of other farm innovations. However, the intellectual influence of the hybrid corn study reached far beyond the study of agricultural innovations, and outside of the rural sociology tradition of diffusion research. Since the 1960s, the diffusion model has been applied in a wide variety of disciplines such as education, public health, communication, marketing, geography, sociology, and economics (Pelto, 1973; Rosen, 2000; Van den Ven et al., 1989; Zaltman et al., 1973). Diffusion studies in these various disciplines have ranged from the rapid diffusion of the Internet to the nondiffusion of the Dvorak keyboard (in typewriters and computers). The innovations that have been studied in diffusion research have mainly been technological innovations.

Diffusion is the process by which (1) an innovation (2) is communicated through certain channels (3) over time (4) among the members of a social system (Rogers, 1995). Diffusion is a special type of communication concerned with the spread of messages that are perceived as new ideas, and necessarily represents a high degree of uncertainty to the individual. The four main elements in the diffusion of new ideas are (1) the innovation, (2) communication channels, (3) time, and the social system.

[†] Deceased

The Innovation

An innovation is an idea, practice, or object that is perceived as new by an individual or other unit of adoption. The characteristics of an innovation, as perceived by the members of a social system, determine its rate of adoption. Some innovations diffuse relatively slower, and other innovations diffuse faster. Why do certain innovations spread more quickly than others? The characteristics which determine an innovation's rate of adoption are: (1) relative advantage, (2) compatibility, (3) complexity, (4) trialability, and observability.

Relative Advantage

This is the degree to which an innovation is perceived as better than the idea it supersedes. The degree of relative advantage may be measured in economic terms, but social prestige, convenience, and satisfaction are also important factors. It does not matter so much if an innovation has a great deal of objective advantage. What does matter is whether an individual perceives the innovation as advantageous. The greater the perceived relative advantage of an innovation, the more rapid its rate of adoption will be.

Compatibility

This is the degree to which an innovation is perceived as being consistent with the existing values, past experiences, and needs of potential adopters. An idea that is incompatible with the values and norms of a social system will not be adopted as rapidly as an innovation that is compatible. The adoption of an incompatible innovation often requires the prior adoption of a new value system, which is a relatively slow process.

Complexity

This is the degree to which an innovation is perceived as difficult to understand and use. Some innovations are readily understood by most members of a social system; others are more complicated and will be adopted more slowly. New ideas that are simpler to understand are adopted more rapidly than innovations that require the adopter to develop new skills and understandings.

Trialability

This is the degree to which an innovation may be experimented with on a limited basis. New ideas that can be tried on the

installment plan generally will be adopted more quickly than innovations that are not divisible. An innovation that is trialable represents less uncertainty to the individual who is considering it for adoption, who can learn by doing.

Observability

This is the degree to which the results of an innovation are visible to others. The easier it is for individuals to see the results of an innovation, the more likely they are to adopt it. Such visibility stimulates peer discussion of a new idea, as friends and neighbors of an adopter often request innovation-evaluation information about it.

Communication Channels

The second main element in the diffusion of new ideas is the communication channel. Communication is the process by which participants create and share information with one another in order to reach a mutual understanding. A communication channel is the means by which messages get from one individual to another. Mass media channels are more effective in creating knowledge of innovations, whereas interpersonal channels are more effective in forming and changing attitudes toward a new idea, and thus in influencing the decision to adopt or reject a new idea. Most individuals evaluate an innovation, not on the basis of scientific research by experts, but through the subjective evaluations of near-peers who have adopted the innovation. So the process is essentially social in nature, being driven by individuals talking to others about the new idea, as they give meaning to the innovation.

Time

The third main element in the diffusion of new ideas is time. The time dimension is involved in diffusion in three ways.

Innovation-Decision Process

First, time is involved in the innovation-decision process. The innovation-decision process is the mental process through which an individual (or other decision-making unit) passes from first knowledge of an innovation to forming an attitude toward the innovation, to a decision to adopt or reject, to implementation of the new idea, and to confirmation of this decision. An individual seeks information at various stages in the innovation-decision process in order to decrease uncertainty about an innovation's expected consequences.

Innovativeness

The second way in which time is involved in diffusion is in the innovativeness of an individual or other unit of adoption. Innovativeness is the degree to which an individual or other unit of adoption is relatively earlier in adopting new ideas than other members of a social system. There are five adopter categories, or classifications of the members of a social system on the basis on their innovativeness: (1) innovators, (2) early adopters, (3) early majority, (4) late majority, and (5) laggards.

Innovators

These are the first 2.5% of the individuals in a system to adopt an innovation. Venturesomeness is almost an obsession with innovators. This interest in new ideas leads them out of a local circle of peer networks and into more cosmopolite social relationships. Communication patterns and friendships among a clique of innovators are common, even though the geographical distance between the innovators may be considerable. Being an innovator has several prerequisites. Control of substantial financial resources is helpful to absorb the possible loss from an unprofitable innovation. The ability to understand and apply complex technical knowledge is also needed. The innovator must be able to cope with a high degree of uncertainty about an innovation at the time of adoption. While an innovator may not be respected by the other members of a social system, the innovator plays an important role in the diffusion process: that of launching the new idea in the system by importing the innovation from outside of the system's boundaries. Thus, the innovator plays a gatekeeping role in the flow of new ideas into a system.

Early adopters

These are the next 13.5% of the individuals in a system to adopt an innovation. Early adopters are a more integrated part of the local system than are innovators. Whereas innovators are cosmopolites, early adopters are localites. This adopter category, more than any other, has the greatest degree of opinion leadership in most systems. Potential adopters look to early adopters for advice and information about the innovation. This adopter category is generally sought by change agents as a local missionary for speeding the diffusion process. Because early adopters are not too far ahead of the average individual in innovativeness, they serve as a role-model for many other members of a social system. The early adopter is respected by his or her peers, and is the embodiment of successful, discrete use of new ideas. The early adopter knows that to continue to earn this esteem of colleagues and to maintain a central position in the communication networks of the system, they must make judicious innovation-decisions. The early adopter decreases uncertainty about a new idea by adopting it, and then conveying a subjective evaluation of the innovation to near-peers through interpersonal networks.

Early majority

This is the next 34% of the individuals in a system to adopt an innovation. The early majority adopt new ideas just before the average member of a system. The early majority interact frequently with their peers, but seldom hold positions of opinion leadership in a system. The early majority's unique position between the very early and the relatively late to adopt makes them an important link in the diffusion process. They provide interconnectedness in the system's interpersonal networks. The early majority are one of the two most numerous adopter categories, making up one-third of the members of a system. The early majority may deliberate for some time before completely adopting a new idea. 'Be not the first by which the new is tried, nor the last to lay the old aside,' fits the thinking of the early majority. They follow with deliberate willingness in innovations, but seldom lead.

Late majority

This is the next 34% of the individuals in a system to adopt an innovation. The late majority adopt new ideas just after the average member of a system. Like the early majority, the late majority make up one-third of the members of a system. Adoption may be the result of increasing network pressures from peers. Innovations are approached with a skeptical and cautious air, and the late majority do not adopt until most others in their system have done so. The weight of system norms must definitely favor an innovation before the late majority are convinced. The pressure of peers is necessary to motivate adoption. Their relatively scarce resources mean that most of the uncertainty about a new idea must be removed before the late majority feel that it is safe to adopt.

Laggards

These are the last 16% of the individuals in a system to adopt an innovation. They possess almost no opinion leadership. Laggards are the most localite in their outlook of all adopter categories; many are near isolates in the social networks of their system. The point of reference for the laggard is the past. Decisions are often made in terms of what has been done previously. Laggards tend to be suspicious of innovations and change agents. Resistance to innovations on the part of laggards may be entirely rational from the laggard's viewpoint, as their resources are limited and they must be certain that a new idea will not fail before they can adopt.

Rate of Adoption

The third dimension in which time is involved in diffusion is in rate of adoption. The rate of adoption is the relative speed with which an innovation is adopted by members of a social system. The rate of adoption usually is measured as the number of members of the system that adopt the innovation in a given time period. As shown previously, an innovation's rate of adoption is influenced by the five perceived attributes of an innovation.

The Social System

The fourth main element in the diffusion of new ideas is the social system. A social system is defined as a set of interrelated units that are engaged in joint problem-solving to accomplish a common goal. The members or units of a social system may be individuals, informal groups, organizations, and/or subsystems. The social system constitutes a boundary within which an innovation diffuses. How the system's social structure affects diffusion has been studied. A second area of research involved how norms affect diffusion. Norms are the established behavior patterns for the members of a social system. A third area of research has had to do with opinion leadership, the degree to which an individual is able to influence informally other individuals' attitudes or overt behavior in a desired way with relative frequency. A change agent is an individual who attempts to influence clients' innovation-decisions' in a direction that is deemed desirable by a change agency.

A fourth type of research involves the types of innovation-decisions (whether individual adoption decisions or organizational decisions, and whether they are made by an authority or by consensus). Another type ofresearch, conducted mainly by anthropologists, analyzed the consequences of innovation.

A crucial concept in understanding the nature of the diffusion process is the critical mass, which occurs at the point at which enough individuals have adopted an innovation that the innovation's further rate of adoption becomes self-sustaining. The concept of the critical mass implies that outreach activities should be concentrated on getting the use of the innovation to the point of critical mass. These efforts should be focused on the early adopters, the 13.5% of the individuals in the system to adopt an innovation after the innovators have introduced the new idea into the system. Early adopters are often opinion leaders, and serve as role-models for many other members of the social system. Early adopters are instrumental in getting an innovation to the point of critical mass, and hence, in the successful diffusion of an innovation.

Opinion Leaders

The two-step flow model of mass communication suggests that communication messages flow from a source, via mass media channels, to opinion leaders, who in turn pass them on to followers (Rogers, 1995). This two-step flow model of mass communication can be utilized to diffuse an innovation. The model focuses attention on the inter-media interface between mass media channels and interpersonal communication channels. Mass media channels are primarily creators of awareness-knowledge of innovations, while interpersonal networks are more important in persuading individuals to adopt or reject innovations.

The two-step flow model highlights the importance of opinion leaders in diffusing innovations, and especially in reaching the critical mass. Opinion leaders informally influence other individuals' attitudes or overt behavior in a desired way with relative frequency, so they are critical to the successful diffusion of innovations.

New Communication Technologies

We live in the age of a communication revolution. New and developing communication technologies, and, ultimately, equipment and systems, are influencing the communication industry and American society greatly. Take the Internet, for example. The Internet is a network of interconnected computer systems. By using the Internet as a data highway, an individual can communicate with colleagues and friends at great distance very cheaply, and gain direct access to information in other computer systems. Therefore, diffusion of the Internet has been exceedingly rapid. From 1990 to 2001, the number of individuals adopting the Internet in North America rose from approximately 5 million to 200 million. A huge percentage of the population is interconnected via the Internet. The critical mass in the diffusion of the Internet occurred in about 1989 or 1990, after 20 years of very slow increase in the rate of adoption of computer networks.

Most schools and local libraries are connected to the Internet, and can provide Internet access to individuals who otherwise might not own, or have access to, a computer. The potential for

using computer-mediated communication for outreach activities is enormous, and the nature of the diffusion process may be speeding up and becoming less spatially restricted.

Abstract

This article first outlines the various models of evolution that have been proposed, including the Darwinian theory and the most popular alternatives. It then outlines the early development of ideas about how life could have developed, including the Lamarckian theory of the inheritance of acquired characteristics. The development and publication of Darwin's theory is described, along with the controversies following its publication. Efforts to promote alternative theories in the late nineteenth century are described and the implications of the various theories for ideas about human origins and social evolution noted. The article concludes with the emergence of modern Darwinism and later debates such as those arising from sociobiology and evolutionary developmental biology.

The term 'evolution' is widely used to denote the development through time of societies, cultures, and more especially of living species. It is often contrasted with the view that these entities were divinely created as we see them today, and is routinely (but incorrectly according to modern biological theory) associated with the idea of progress. This article outlines the various models of evolution that have been suggested to account for the development of life and social organization, and then shows how the theories were formulated and popularized. Particular attention is paid to the work of Charles Darwin, whose theory of biological evolution by natural selection is now seen as the most influential expression of the basic idea of natural development. However, non-Darwinian evolutionary ideas also played a role in biology and were perceived to have implications for social evolution.

Models of Evolution

The term 'evolution' is derived from the Latin *evolutio*, denoting the unrolling of a scroll. In the eighteenth century it was applied to the growth of the embryo, then often described as the mere expansion of a preformed miniature. This application was retained up to the nineteenth century, by which time it was clear that the development of the embryo consisted of the progressive appearance of more complex structures. The philosopher and sociologist Herbert Spencer generalized the term by applying it to any process of natural progressive development, thereby creating the still common but inaccurate belief that all evolution must be progressive. In particular, Spencer applied the term to the development of societies and of life on earth.

Charles Darwin did not often use the term when describing his theory of the origin of species, but by the end of the nineteenth century, this had become the most common version of 'evolution.' However, Darwin's theory did not imply an inevitable progression toward complexity, and much controversy has surrounded the association between evolution and progress. Darwin's theory of natural selection now dominates biology and is being extended to many other domains; it is but one of a number of mechanisms that have been suggested to explain evolution, each of which has its own associated implications.

The Ladder of Progress

Perhaps the most popular model of evolution, and one that reveals the link with embryology, is of a linear hierarchy of stages of development from inception to maturity. Such a model simply assumes that all change is progressive and that there is only one direction of development. When applied to societies or species, the model can be adapted by supposing that many lines of development each ascend the same hierarchy but at different rates, so that the slow developers illustrate the ancestral stages already passed through by those at the top of the scale.

Evolutionary Trees

Although the ladder model is still popularly applied to the evolution of life on earth, and was once accepted in the social sciences, biologists and sociologists now realize that there is no single goal toward which evolution is developing – neither the human race nor Western civilization can be treated as the most mature phase of development. Evolution is better represented as a tree or a bush with many branches, each of which is constantly subdividing. The end product of one branch cannot be seen as the goal toward which all the others are ascending, and it is impossible for the end product of one branch to illustrate exactly the ancestral form of another branch. The living apes are not immature humans, because even if the common ancestor from which humans and apes have evolved would be classified as an ape, it would no longer be identical to any of the living ape species. If there is progress on the branching tree model, it has to be defined in more sophisticated terms so that there are many different ways to become more complex.

Darwin argued that branching evolution explains how we are able to classify species into groups within groups (species, genera, families, etc.). Two species descended from a common ancestor will still share many characters derived from that ancestor, and will share some characters with even more distant relatives. Darwin and his modern followers assume that each new character is developed only once, so all species exhibiting the character are descended from a common ancestor that also had the character. This assumption will be invalidated if there are cases where two lines of evolution evolve the same character independently (convergence or homoplasy). It will also be

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81005-3

invalidated if there are even small-scale examples of ladderlike evolution, where several branches are constrained to evolve along the same pattern of development (parallelism).

Adaptation

The branching model had already been applied to the evolution of languages before Darwin and his followers used it to transform biology. Darwin's key insight was that there was no natural mechanism that could force evolution along a single predetermined path. Evolution is driven not by progress but by the necessity for each species to adapt to its environment in an ever-changing world. Branching occurs because a single population can sometimes become divided by a geographical barrier, after which each isolated population will develop independently in response to the different adaptive pressures it encounters. Progress to a more complex structure is at best a by-product of adaptation and is never inevitable in any one branch; indeed, many species are the products of degenerative evolution. In the animal kingdom, two branches of evolution can seldom if ever rejoin via hybridization (although this does happen in plants). Here, there is a clear contrast with social and linguistic evolution, where mergings and borrowings are frequent.

Darwinism and Lamarckism

Two mechanisms of adaptive evolution have been suggested: natural selection (Darwinism) and the inheritance of acquired characters (Lamarckism). Darwin assumed that the species consists of a population of organisms that exhibit some degree of individual variation and that these variations are inherited – we now explain them as genetic differences produced by mutations. He argued that if the population is exposed to a new environment, some variants will by chance be able to cope better with the new conditions; they will survive and reproduce, transmitting their favorable characters to the next generation. Any that are less fitted to the environment will be unlikely to breed and may even die, so their characters are eliminated from the population. Over many generations, this process of natural selection (Spencer called it the 'survival of the fittest') will change the species to adapt it to the environment.

Some time before Darwin, J.B. Lamarck proposed that the inheritance of characters acquired during an organism's lifetime could accumulate to give adaptive transmutation. An acquired character is produced by the organism's behavior, which in the wild is usually a response to the environment. Thus, the ancestral giraffes, striving to reach the leaves of trees as an alternative source of food, were able to lengthen their necks, just as a weightlifter can acquire better developed muscles. If such characters are inherited, the next generation of giraffes would be born with longer necks and would then stretch them further. This mechanism was once popular in biology, and corresponds quite closely to how humans transmit new ideas to their descendants. However, where teaching and learning provide a natural mechanism for ideas to be transmitted, modern genetics has shown that there is no way in which acquired biological characters can be inherited. Lamarckism has been banished from biology: The giraffe got its long neck because those who by chance inherited the genes producing that trait reproduced faster than those who carried the genes for shorter necks. The genetic differences are the product of mutations that are random as far as the requirements of the species are concerned.

Nonadaptive Evolution

There are also several mechanisms of biological evolution that suppose that not all developments are adaptive. In the nineteenth century, many naturalists believed that evolution was the unfolding of a predetermined pattern, perhaps analogous to or controlled by the forces of embryological development. Such ideas gave rise to the theory of recapitulation, which supposes that the evolutionary history of the species is traced out by the development of the embryo (or 'ontogeny recapitulates phylogeny'). This in turn suggests a model of evolution more in tune with the notion of a hierarchical ladder of development. The possibility that saltations (evolutionary jumps or macromutations) might have found new populations was once taken seriously even by geneticists. The theory of orthogenesis supposed that the species was somehow programmed to vary continuously in a particular direction, forcing groups of species to evolve in parallel. Such ideas are now largely discounted in biology, although the possibility that there might be constraints on the range of possible variation has recently been taken more seriously by the advocates of evolutionary developmental biology or 'evo-devo.' In the social sciences, the question of whether all cultural and social differences serve a practical purpose has been much debated, and this debate continues.

Pre-Darwinian Evolutionism

Darwin's was not the first theory of evolution, although the publication of his *Origin of Species* in 1859 triggered the conversion of most scientists to evolutionism. Several earlier versions of the idea were proposed, and although rejected by conservative thinkers and most scientists, they did much to prepare the way for the reception of Darwinism (Bowler, 1989c).

Creation and Design

The early Church Fathers did not take the Genesis story of creation in the Bible literally, and it was the Protestant theologians of the seventeenth century who established the worldview that survives in modern 'young earth' creationism. Archbishop James Ussher published his much ridiculed calculation that the earth was created in 4004 BC. In such a climate of opinion, a form of natural theology flourished in which it could be argued that God had designed and created all the modern species just as we see them today, each with the structures and instincts appropriate for its intended habitat. John Ray and many other naturalists stressed the adaptation of species to their environment, and argued that similarities could be used to classify species because they expressed the rational order of God's plan of creation – a view adopted by Carolus Linnaeus, who founded the modern system of biological classification (Greene, 1959). Others exploited the ancient concept of the 'chain of being,' in which the plan of creation was a linear hierarchy, with the human species at the top of the animal series. This was promoted without any sense of progression

through time, although the influence of the chain was retained in some of the early theories of progressive evolution.

Evolution in the Enlightenment

The more radical thinkers of the eighteenth-century Enlightenment recognized that the Earth was much older than Ussher's estimate and that the planet had changed considerably in the course of its history. Some explored the possibility that life had been produced by spontaneous generation from nonliving matter, and began to doubt that species remained unchanged through time. The French naturalist Georges Leclerc, Comte de Buffon, was especially influential in this respect, as were the materialist philosophers Denis Diderot and Baron d'Holbach (Roger, 1998).

Toward the end of the eighteenth century, Erasmus Darwin (grandfather of Charles) published a theory of transmutation in his *Zoonomia*, arguing that all living things were derived from a simple origin and had become more complex through their striving to adapt to the environment. These views were echoed in a more sophisticated form in J.B. Lamarck's *Zoological Philosophy* of 1809. Lamarck accepted that there was a basic progressive force driving living things to ascend the chain of being over many generations, but he accepted that no linear pattern is visible in the present animal and plant kingdoms, explaining the divergence as a consequence of life's constant need to adapt to an ever-changing environment. He invoked the inheritance of acquired characters (described above) to explain this process, and his name has been associated with that mechanism ever since (Corsi, 1988).

The Fossil Record

Historians used to think that Lamarck was marginalized by his great rival, Georges Cuvier, who pioneered the study of fossil bones to reconstruct the history of life. Cuvier showed that there was a succession of populations in the course of the earth's history but insisted that species disappear abruptly from the record through the action of geological catastrophes. He rejected transmutation but did not openly endorse the idea of divine creation – although the theory of a succession of creations was popularized by Cuvier's British followers, including William Buckland. Although they had extended the Earth's history, Cuvier and Buckland were convinced that the human race was a recent creation. Their work thus endorsed a view of human history in which there was no time for social evolution, many scholars still believing that language and the arts of civilization were taught to the earliest humans by their Creator.

Later historical work has shown that although the theory of successive creations was endorsed by the scientific establishment, more radical thinkers in both France and Britain were attracted to Lamarck's theory (Desmond, 1989). Darwin, who developed his theory in the 1830s, concealed it for fear of being associated with this radical movement. Historians also now recognize that there was an alternative non-Darwinian theory of evolution emerging in Germany among the followers of J.F. Blumenbach. This stressed the model of preordained development and invoked the parallel with embryological development. The situation in Britain changed significantly following the anonymous publication of Robert Chambers' *Vestiges of the Natural History of Creation* in 1844 (Secord, 2000). Chambers argued that an ideology of progress was just what the middle class needed to support its demands for reform, and provided a scientific foundation for this ideology based on the idea of progressive evolution. Although he presented evolution as the unfolding of a divine plan, his book's open recognition that humans are transformed animals, and that the mind is a product of the expansion of the brain, caused an outcry from conservative thinkers. Over the following decade, however, *Vestiges* popularized the idea of progressive evolution, creating a space in which Darwin's more scientific theory could have an impact.

The Development of Darwin's Theory

Charles Darwin was converted to evolutionism by his discoveries on the voyage of HMS *Beagle* (1831–36) and returned to England determined to understand how the process worked. He soon discovered the mechanism of natural selection and continued to work on the various aspects of his theory in relative secrecy. Much controversy has surrounded Darwin's discovery, because in addition to the many scientific factors influencing his thinking, he acknowledged the impact of Thomas Malthus' principle of population, a product of the ideology of laissez-faire economics.

Scientific Influences

While studying at Cambridge, Darwin was attracted to William Paley's Natural Theology of 1802, which restated the argument that species are adapted to their environment through the wisdom and benevolence of the Creator. On the voyage of the *Beagle*, his observations of South American geology converted him to Charles Lyell's uniformitarian position, which accounted for all geological change in terms of the action of observable forces over vast periods of time. Biogeographical studies, especially those of the birds of the Galapagos Islands, forced him to rethink the idea of Divine Creation, because he saw that individual islands had each acquired a distinct species of immigrant families, such as the finches. On his return to England, he soon accepted a complete evolutionary philosophy and began to search for a mechanism (Browne, 1995).

Darwin saw that evolution must be a branching process and that the ultimate cause was the adaptation of isolated populations to different environments. He studied animal breeding and realized that breeders produce new varieties by selecting out individual animals with the required character and breeding only from these. Artificial selection draws on the natural and largely random variability of the population and allows only individuals with a selected character to breed, thereby enhancing that character in future generations. Darwin was soon looking for a natural equivalent of this process.

Malthus and Population

A vital step in Darwin's thinking came when he read Malthus' *Essay on Population*, which argued that populations breed so rapidly that they outstrip their food supply. Drawing on hints in Malthus, Darwin realized that population pressure must generate a struggle for existence in which many individuals die.

He was now able to argue that any better adapted variant would be more successful in the struggle and would be more likely to survive and reproduce, while poorly adapted variants would die, thus establishing the theory of natural selection described in Section Darwinism and Lamarckism. This gave Darwin the basis on which to erect a comprehensive account of evolution. The role played by Malthus' ideologically loaded principle has, however, led to frequent charges that Darwin's theory is itself a projection of laissez-faire values on to nature, with the consequence that the theory would be used to justify the competitive ethos of Victorian capitalism (Young, 1985). Much controversy also surrounds the degree of Darwin's commitment to the idea of progress. Although the selection theory undermines the ladder model of progress, historians now accept that Darwin's thinking was influenced by the assumption that competition is the driving force of a more general form of progress. However, it is clear that Darwin's commitment to branching evolution went far beyond the conventional social values later linked to his theory, while his application of the population principle undermined Malthus' own ideology, which was an attempt to discredit the optimism of social progressionists.

Darwin let only a few close contacts know of his theory, while continuing to work on exploring its scientific implications. He came to appreciate that, even in a stable environment, specialization would allow natural selection to continue the process of divergence by which species separate from close relatives. Eventually, he began to write up his ideas for publication but was interrupted in 1858 by the arrival of a paper by Alfred Russel Wallace describing a similar (although not identical) theory. The joint Darwin–Wallace papers were published in that year, while Darwin rushed to complete the *Origin of Species* (Browne, 2002).

Darwinism in Biology

The *Origin of Species* sparked an intense debate that soon led to the conversion of most scientists and educated people to evolutionism (Hull, 1973; Ruse, 1979). Despite initial opposition by conservative thinkers, the belief that the human race was the outcome of a progressive trend built into nature was accepted. In science, too, creationism was replaced by the expectation that all living species are the products of natural processes, and here, too, there was a widespread assumption that such processes guaranteed progress, even if superimposed on a branching model of development. The success of Darwinism needs to be assessed with care because the popularity of this developmental model of evolution meant that the more radical implications of Darwin's thinking were evaded (Bowler, 1988). Far from welcoming the theory of natural selection, most nineteenth-century scientists, including some of Darwin's leading supporters, were lukewarm about it. Opposition grew toward the end of the century, with many alternative mechanisms of evolution being tried out.

The History of Life

Much of the first generation of evolutionists' efforts focused on reconstructing the course of the history of life on earth from anatomical, embryological, biogeographical, and fossil evidence (Bowler, 1996). Darwin himself treated this project with caution, but under the influence of the German biologist Ernst Haeckel, a whole generation of evolutionists strove to complete it. They had some successes, but the problems were much greater than they had anticipated and the project was sidelined by new developments in biology at the beginning of the twentieth century. Darwin had stressed the imperfection of the fossil record, but in a few important areas new discoveries helped to show how the major steps in evolution had taken place. Elsewhere, anatomical and embryological evidence was used to reconstruct evolutionary relationships. Darwin's theory implied that it would be unlikely for the same character to develop independently in different lines of evolution, so similarity of underlying structure could be taken as evidence of common descent. Some non-Darwinian theories, however, postulated predetermined trends that might generate similar structures independently. In embryology, Darwin's assumption that early stages of development would illustrate affinities was overtaken by Haeckel's recapitulation theory, according to which earlier stages could actually illustrate ancestral adult forms. This way of thinking was a product of the progressionist way of thought, presupposing a privileged line of development toward maturity. Only in biogeography did it become clear that evolution was a highly irregular process, depending on the hazards of migration in a world where geological forces were constantly remolding the topography.

Natural Selection and the Alternatives

Historians have focused on the debates over natural selection, but this is more a product of our modern preoccupation with that mechanism than of its significance in late nineteenth-century biology. One much discussed theme centers on Darwin's concept of heredity, which was quite unlike the model of unit character inheritance promoted by Mendelian genetics. It has even been argued that, without the concept of non-blending unit characters, natural selection was fatally flawed. It is true that Darwin was much concerned by Fleeming Jenkins' 1867 review, which argued that if male and female parental characters blend in the offspring, the advantages of a well-favored 'sport' or mutation would be diluted rapidly. However, as A.R. Wallace pointed out, this objection is irrelevant if there is a continuous range of variation in the population, which is the case for most characters (Gayon, 1998).

In fact, many of the objections to natural selection were intended only to show that evolution must be a more purposeful process than any mechanism based on random variation would allow. One major alternative that now became popular was the Lamarckian theory of the inheritance of acquired characters, in which the animals' own behavior directs their variation. Some objections to natural selection were aimed at the whole idea of adaptive evolution and were intended to show that some internally driven force directed the organisms' variation. These were very much a product of the rival developmental tradition that had become popular earlier in the century, especially in Germany. The theory of orthogenesis supposed that variation was controlled by internal developmental forces that generated linear evolutionary trends, while the theory of saltations assumed that macromutations could somehow find new breeding populations (Bowler, 1983).

Human Origins and Social Evolution

Many religious thinkers objected to the idea that the human soul was the product of evolution from an animal ancestry. Much of this initial opposition was overcome by stressing the purposeful nature of evolution, allowing the appearance of humanity to be presented as the culmination of a divine plan (Moore, 1979). Darwin's theory of evolution threatened this assumption, and in his *Descent of Man* of 1871, he argued that humans had evolved from African apes, which had stood upright as an adaptation to a new lifestyle on the open plains. Most late nineteenth-century accounts of human evolution, however, stressed the expansion of the brain as the main driving force of the process. At the same time, the idea of progressive evolution was applied to the history of human cultures and societies. Some evolutionists, including Spencer, stressed competition as the driving force of progress, leading to the charge that they were promoting a 'social Darwinism' designed to legitimize capitalist values. While Darwin's theory was certainly associated with this movement, it was by no means the only scientific justification offered.

Cultural Evolutionism

Coincidentally with the Darwinian revolution, archaeologists undermined the belief that the human race was a recent creation, and exposed a vast period of prehistory in which our ancestors had used only stone tools. It was this initiative rather than any influence from Darwinism that led anthropologists such as Edward B. Tylor to equate modern 'savages' (i.e., people with relatively unsophisticated technology) with the ancestral stages through which civilized humans had passed in prehistoric times on their march toward a more mature culture. Cultural evolutionism was a product of the nineteenth-century developmental viewpoint, based on the ladder model of progress (Bowler, 1989a). Tylor himself did not accept that humans had evolved from apes, but other cultural evolutionists, especially John Lubbock, linked the two modes of evolution and argued that 'savages' were biologically as well as culturally primitive – living examples of the earlier stages in human biological and mental evolution. Herbert Spencer's model of social evolution, while stressing ostensibly the divergent nature of evolution, still presented 'lower' races as surviving primitives incapable of matching the mental powers of the Anglo-Saxons.

Social Darwinism

Spencer is most often remembered, however, as the social philosopher who linked the idea of progress to the ideology of free enterprise individualism. As an exponent of laissez-faire, and the coiner of the term 'survival of the fittest,' it has been easy for critics to portray Spencer's enthusiasm for struggle as the motor of progress as a direct application of the Darwinian selection theory to society, hence the image of him as the founder of 'Social Darwinism.' Spencer worried about the elimination of the unfit, but in biology he defended Lamarckism, and his enthusiasm for struggle came more from a conviction that competition would stimulate individual self-improvement (which in a Lamarckian scheme could be passed on to future generations). Darwin's theory is thus only one of the scientific factors that stimulated the ideology of 'progress through struggle' – remembered preferentially because natural selection has now become the only mechanism by which that metaphor can be put into practice in biology (Bannister, 1979). In the later nineteenth century, there was more emphasis on the struggle between nations and races, which bypasses the central feature of natural selection within populations.

Modern Darwinism

By the end of the nineteenth century, the attempt to reconstruct the courses of biological and social evolution had run out of steam. The social sciences abandoned the evolutionary model and any suggestion that human behavior is predetermined by biological factors. Biologists began to study the actual processes of heredity and variation, leading to the emergence of Mendelian genetics. The geneticists destroyed Lamarckism, and although at first hostile to the selection theory, they were eventually convinced that genetic mutation was the source of the random variation that is the raw material of natural selection. By the mid-twentieth century, the 'Modern Synthesis' of Darwinism and genetics had come to dominate biology but remained controversial elsewhere.

The Modern Darwinian Synthesis

In the last decade of the nineteenth century, the statistician Karl Pearson developed a mathematical model of natural selection acting on the variations in a wild population (Gayon, 1998). Many biologists were now exploring the idea that new species were produced by saltations or macromutations, and it was partly from this tradition that the 'rediscovery' of Gregor Mendel's laws of particulate inheritance emerged. Ignored since the 1860s, these laws postulated the existence of unit characters transmitted unchanged from one generation to the next. In 1900, Mendel's laws were proclaimed as the basis for a new science of heredity, which William Bateson soon called 'genetics.' However, Pearson was already hostile to Bateson's saltationism, while Bateson rejected Pearson's commitment to continuity and adaptation. Genetics was thus perceived as a new alternative to Darwinism, although it destroyed the credibility of Lamarckism by suggesting that there is no plausible way in which acquired characters can affect the gene (Bowler, 1989b).

T.H. Morgan's studies of genetic mutations showed that most macromutations are fatal, while small mutations simply add to the genetic variation in the population. Soon, Morgan conceded that natural selection would affect the reproductive success of the various genes. In the 1920s and 1930s, R.A. Fisher, J.B.S. Haldane, and Sewall Wright brought together the statistical study of populations with the new genetics to create a science of population genetics based on the genetic theory of natural selection (Provine, 1971; Mayr, 1982). Naturalists such as Julian Huxley and Ernst Mayr now recognized that the adaptation of local populations to their environment was the most likely explanation of how species originate. The new selection theory was integrated with these wider developments to create what Huxley called the 'Modern Synthesis.'

Later Developments

The Darwinian synthesis has dominated biology since the mid-twentieth century, although there have been numerous developments within it and some efforts to limit its applicability. Some modern thinkers now argue that the concept of natural selection can be applied to almost all areas where change is observed, sweeping away the whole idea of a universe that is the product of divine purpose. Conversely, the emergence of evolutionary developmental biology (evo-devo) has renewed interest in the role of embryological factors in the creation of new characters and has thereby reinstated some topics that were central to the non-Darwinian programs of the nineteenth century (Amundson, 2005).

Perhaps the most controversial applications of modern biology are efforts to apply the theory of natural selection to human beings, especially in the area of social behavior. The science of sociobiology has been successful in explaining the social behavior of animals in terms of genetics and reproductive success, via the concept of the 'selfish gene' (Dawkins, 1976). However, E.O. Wilson's efforts to apply sociobiology to human behavior by suggesting that we are driven by instincts implanted by natural selection have been greeted with much suspicion by social scientists and have also been dismissed as a revived 'social Darwinism' by the political left (Segerstrale, 2000). In more recent decades, sociobiology has been replaced by evolutionary psychology, which postulates that human behavior is shaped by inbuilt behavioral constraints evolved originally to deal with the environment in which the earliest modern humans evolved (Barkow et al., 1992). This approach depicts the mind as a collection of more or less independent modules controlling behavior, rather than as a generalized information processor. It is opposed by rival methodologies including human behavioral ecology and a new form of cultural evolutionism, both of which focus on the malleability of behavior and our ability to respond to current environmental and social pressures. The question of how much evolutionary biology can tell us about operations of the human mind thus remains controversial.

Abstract

The development of theories of biological evolution and theories of social or cultural evolution is briefly surveyed. The question of empirical content is kept in the foreground. Contemporary theories of social evolution are at an earlier stage of development than contemporary theories of biological evolution. There is no counterpart to molecular genetics. However, contemporary theories of cultural evolution are not content free. They do generate some testable models.

In its most minimal sense, 'evolution' simply means gradual change by some natural process. In this sense, belief that species of plants and animals have evolved is at least as old as Aristotle's contrary belief in the fixity of the species. The theory of evolution acquires more content as the nature of the natural process involved is specified.

Darwin (1859) provided the broad outlines of the modern theory. There are traits that are inherited. There is some process that produces natural variation in these traits. The traits may affect the ability of the organism to reproduce, and thus the average number of individuals bearing the traits in the next generation. Therefore, those traits that enhance reproductive success increase in frequency in the population, and those that lead to below average reproductive success decrease in frequency. The three essential factors in Darwin's account are (1) natural variation, (2) differential reproduction, and (3) inheritance. The questions of the existence, extent, and nature of these factors are empirical scientific questions.

Could these processes, as they naturally occur, account for large changes over time? Darwin argued that they could by calling attention to the large changes that had come about from the selective breeding of plants and animals. Selective breeding is just a particularly severe form of differential reproduction, imposed by the breeder. Darwin emphasized this argument by calling his theory a theory of natural selection:

> I have called this principle, by which each slight variation, if useful, is preserved, by the term Natural Selection, in order to mark its relation to man's power of selection. But the expression often used by Mr. Herbert Spencer, of the Survival of the Fittest, is more accurate, and is sometimes equally convenient. We have seen that man by selection can certainly produce great results, and can adapt organic beings to his own uses, through the accumulation of slight but useful variations, given to him by the hand of Nature. But Natural Selection, as we shall hereafter see, is a power incessantly ready for action, and is as immeasurably superior to man's feeble efforts, as the works of Nature are to those of Art. (Darwin 1859, Origin of the Species, 6th edn., Chap. III)

The status of Spencer's description has been a matter of controversy. On superficial reflection on the slogan, survival of the fittest, more than one commentator has asked: "If fitness is fitness to survive, is not the theory of survival of the fittest simply a tautology?" We can give a preliminary examination of this idea in a highly idealized setting. Let us take Darwinian fitness just to mean expected number of offspring. Let us suppose that the population is effectively infinite, so that the expected number of offspring for a type can be taken to equal the average number of offspring. Let us suppose that reproduction is asexual and transmission of a type is perfect. If we had one generation every time unit, these assumptions specify a dynamics of population proportions called the discrete time replicator dynamics. Taking generations close together, or taking overlapping generations, it is possible to idealize to a system of differential equations, which represent the continuous time replicator dynamics (Hofbauer and Sigmund, 1988; Taylor and Jonker, 1978). This is an idealized model of differential reproduction. In this idealized model, one can ask whether it can be proved that the fittest type will go to fixation in the population.

To get any kind of affirmative answer, we must make more assumptions. Suppose that the fitness of a type is fixed. It does not depend on the frequency of types in the population. The environment is considered constant. Suppose that all the types of interest are initially present in the population and that one of them has the greatest Darwinian fitness. Then it is possible to prove that the dynamics will converge to a state of fixation of the fittest strategy, a state where its proportion of the population is 100%. In this sense, survival of the fittest can be mathematically demonstrated.

The demonstration depends not only on the conception of Darwinian fitness but also essentially on a battery of idealizations and assumptions. If the Darwinian fitness of a type is not fixed, but dependent on the frequency of other types in the population, then, even with all the other idealizations in place, the dynamics may not converge to any state at all. (It may cycle or even exhibit chaotic behavior.) If there is a fitter type not present in the population, then differential reproduction provides no way for it to get in. The model can be modified in various ways to allow for mutation, which may introduce the type in question into the population, but then the theorem is no longer true. If the population is finite, then only probabilistic conclusions can be reached. The fittest type may go extinct simply by bad luck. Moreover, in a finite population mutation cannot keep every possible type in play, but rather must be modeled as a chance process that introduces some new types from a very large space of possible types. With the slightest move toward realism the tautology goes away.

In the first half of the twentieth century, Darwinian theory was enriched by Mendelian genetics. Gregor Mendel, an Augustinian monk, had discovered basic principles of genetics

 http://dx.doi.org/10.1016/B978-0-08-097086-8.63025-8

by a series of experiments in plant breeding carried out in the garden of the monastery (Mendel, 1866).

Mendelian genetics introduces a new source of variation in sexually reproducing species, but this variation has its limits. Can recombination of fixed genetic units account for the origin of new species and the whole sweep of Darwinian evolution? Darwinians thought not, and at the beginning of the twentieth century Darwinism and Mendelism were enemies. Only when mutation is included in the picture, so that more fundamental sorts of variation are possible on a longer timescale, is it evident that Mendelism and Darwinism can be thought of as reinforcing each other. This 'modern synthesis' of evolution and genetics was created in the first half of the twentieth century (Dobzhanski, 1937; Fisher, 1930; Haldane, 1932; Wright, 1968, 1969, 1977, 1978).

Mendelian genetics also enriches the account of differential reproduction. We now need to consider reproduction at more than one level. Individuals reproduce but so do genes. Fitness on one level is connected to that on the other, but in a way that can be complicated. The case of heterozygote superiority (as in the case of the sickle cell trait) provides another counterexample to the tautology claim discussed earlier. Heterozygotes cannot take over the population, simply because of the mechanics of genetic reproduction. Frequency-dependent selection reemerges at the level of the gene pool.

Mendelian genetics is a mathematical model (or a set of mathematical models). In 1953, Watson and Crick opened the door to understanding the physical basis of genetics at the molecular level. The dynamics of genetic replication, recombination, mutation, and expression can be studied at this level. The study of molecular genetics has provided many surprises such as the action of retroviruses that can transcribe their own information into the DNA of the host cell, the fact that bacteria can exchange genetic information, and the existence of plasmids – rings of DNA in bacteria that exist and replicate independently of the bacterial chromosome. With the theory of largely adaptively neutral mutations (Kimura, 1968, 1983), molecular genetics has also provided the basis of a molecular evolutionary clock, which can be used to reconstruct evolutionary history.

The history of the theory of biological evolution has been – and will continue to be – a story of the gradual amplification of Darwin's insights by empirical research. The three essential factors in Darwin's account – natural variation, differential reproduction, and inheritance – remain at the center of the theory, but in a form that Darwin could not have imagined.

By social evolution, we mean not the evolution of sociality, which may be one aspect of biological evolution, but rather a social process in some way analogous to the process of biological evolution. What is the analogy to fix upon? Different thinkers have had different aspects of biological evolution in mind (and sometimes, different conceptions of the nature of the biological process). In its most minimal sense, social and cultural evolution can just be thought of as social and cultural change. So interpreted, the theory of social evolution would be such a truism as to lack all interest. Are there deeper and more informative analogies that are worth exploring?

Some thinkers have thought of ideas that can spread through, or disappear from, a population as analogous to genes (Boyd and Richerson, 1985; Campbell, 1965; Cavalli-Sforza and Feldman, 1981; Lumsden and Wilson, 1981). These memes (Dawkins, 1976) can recombine in various ways. (A comprehensive discussion of this topic would have to range from nineteenth century associationalist psychology to modern genetic programming.) They can replicate themselves as they spread from mind to mind. They can be thought of as having a sort of Darwinian fitness in terms of the replicator process.

Others have focused on adaptive dynamics as the appropriate analogy. Darwinian evolutionary models fall, more or less, within a broad class of adaptive models, which also includes various kinds of learning models. In psychological theories of reinforcement learning, it is assumed that there is some 'reward' that is reinforcing, and the theory models the dynamics of behavior under various learning schedules. (The determination of what sort of thing is reinforcing is empirical, but extrinsic to the theory.)

We might then model various dynamical processes of social learning or adaptation instead of trying to model social evolution so as to have a close resemblance to biological evolution.

One common way for individuals to adapt in a social setting is to imitate others whom they observe to be successful according to some generally shared criterion of success. It is a remarkable fact that the replicator dynamics, introduced by Taylor and Jonker (1978) as a mathematical model of differential reproduction, has been derived from a number of different models of learning by imitation in a large population (Binmore et al., 1995; Björnerstedt and Weibull, 1996; Schlag, 1998). The replicator dynamics also has deep connections with classical psychological models of positive reinforcement learning (Borgers and Sarin, 1997; Beggs, 2005).

The replicator dynamics is a member of the broader class of adaptive dynamics according to which all behaviors with greater than average success increase their population proportion, which is a subset of the still broader class according to which the most successful behavior increases its population proportion. These broader classes of adaptive dynamics may also come into play in theories of social evolution (Cressman, 2003; Hofbauer and Sigmund, 2003; Samuelson, 1997; Sandholm, 2010; Weibull, 1995).

Populations may not be large, and encounters may not be random but rather structured. Learning by imitation in such settings may lead to different results than it would lead to in large random mixing populations, just as biological evolution may be affected by population structure and population size (Alexander and Skyrms, 1999; Anderlini and Ianni, 1997; Axelrod and Hamilton, 1981; Epstein, 1998; Frank, 1998; Grim, 1996; Hamilton, 1964; Lindgren and Nordahl, 1994; Nowak and May 1993; Pollack, 1989; Sober and Wilson, 1998; Skyrms, 2003). It is of particular interest that population structure can favor evolution or learning of cooperative behavior in interactions where it would not survive in large random mixing populations.

Classical reinforcement learning is the kind of learning that demands the least thought. A more sophisticated learner might use some kind of inductive reasoning to form beliefs about the aspects of the environment that, together with his/her actions, influence payoffs and then act optimally according to these beliefs. If the relevant aspects of the environment include the actions to be taken by other agents, then the reasoning involved may be complicated, depending on the strategic sophistication

of the agents and the character of the payoffs. (I am trying to predict what she will do. Is she trying to predict what I will do? If so what will she predict and what will she do and what is my best response? But might she be imagining that I am thinking this way? And so forth.) Here there is a whole spectrum of learning models, whose appropriateness depends on the inductive and strategic sophistication of the agents being modeled (Camerer and Ho, 1998; Fudenberg and Levine, 1998; Young, 2004).

If small probabilistic perturbations are added to deterministic dynamics of learning or evolution, then a new kind of equilibrium concept is appropriate, that of a stochastically stable equilibrium. In some cases, the nature of the underlying deterministic dynamics does not matter, and the stochastically stable equilibrium is determined by the payoff structure (Foster and Young, 1990; Kandori et al., 1993; Young, 1993, 2001). A small population with local interaction may reach stochastically stable equilibrium much faster than a large population with random interactions (Ellison, 1993). However, in the context of adaptive social networks, the usual stochastic stability results may be reversed (Skyrms and Pemantle, 2000).

The stage of development of the theory of social evolution is comparable to the earlier stages of the theory of biological evolution. There is no analog of molecular biology in view for social evolution. Rather, there are various mathematical models of learning that can be put to empirical test in special domains of application (Argiento et al., 2009; Blume et al., 1998; Camerer and Ho, 1998, 1999; Cavalli-Sforza et al., 1982; Friedman, 1996; Hewlett and Cavalli-Sforza, 1986; Roth and Erev, 1995; Skyrms, 1996, 2003, 2010; Suppes and Atkinson, 1960; van Huyck et al., 1995).

The processes of biological evolution and social evolution can interact (Boyd and Richerson, 1985; Boyd et al., 2010; Cavalli-Sforza and Feldman, 1981; Crawford, 1989; Richerson and Boyd, 2005). The biological evolution of humans as a social species sets the stage upon which social evolution is carried out. Social structure can feed back to biological evolution by imposing or modifying selective pressures. Basic cultural norms, for instance, the prevailing system of agriculture in a society, can be influenced by the biological evolution of other species. As both Darwin and Mendel observed, they can impose selective pressures on domesticated plants and animals. When cultural changes allow humans to survive in new or modified environments, selective pressures on humans themselves can be modified, as emphasized by Baldwin (1902). As humans continue to transform the planet, the biological effects of human cultural evolution become more and more extensive.

Evolutionary Approach to Education Science

David C Geary, University of Missouri at Columbia, Columbia, MO, USA

Abstract

Evolution has resulted in a system of evolved cognitive abilities that coalesce around the domains of folk psychology, biology, and physics. These cognitive domains direct attention toward and process information about other people, the flora and fauna in the local ecology, and the physical environment. Among the associated competencies are language, the ability to interpret facial expressions, knowledge of the behavior of familiar animals, and the ability to navigate in the physical world. The basic architecture of these competencies is universal and adapted to the nuances of local conditions as children play, interact with other people, and explore the environment. In modern societies, people must also acquire a host of cognitive competencies that have not evolved, including reading, writing, and basic mathematics. The learning of these nonevolved competencies requires adapting evolved cognitive systems for tasks for which they are not designed. The associated activities (e.g., direct instruction) appear to be very different from the activities (e.g., play) that foster the adaptation of evolved abilities to local conditions. Schooling thus involves the society-wide organization of children's activities, such that they learn competencies that would not otherwise emerge.

During the past decade, evolutionary analyses of human behavior, social relationships, and cognition have become increasingly common within psychology, albeit not without continued resistance from some social scientists. The goals here are to consider how theory and research in evolutionary psychology can be used to understand children's cognitive and academic development and to explore related educational issues, a subfield now known as evolutionary educational psychology (Geary, 2012a). This approach is illustrated with discussion of how evolved cognitive abilities, specifically language, can be modified through schooling to create evolutionarily novel ones, specifically reading, and with discussion of the attendant implications for understanding children's achievement motivation. Before these issues can be fully appreciated, an overview of the evolutionary approach to cognition and development is needed.

Evolution and Cognition

The basic assumption of evolutionary psychologists is that the human brain and cognitive abilities evolved to attend to, process, and guide behavioral response to evolutionarily significant information that coalesces around folk psychology, folk biology, and folk physics (see Geary, 2005). These biologically primary or core domains are predicted to be modular to the extent that they are biased to process specific forms of information; and they are predicted to be plastic to the extent that sensitivity to variation in the corresponding information patterns provides an advantage. A bias to orient to the human face and to automatically process key pieces of facial information (e.g., eyes) is an example of a modular primary ability (Kanwisher et al., 1997) that in this case is a component of folk psychology. If the ability to discriminate one person from the next affords a social advantage over those who cannot make these discriminations, then this modular system will evolve some degree of plasticity, but within constraints.

A taxonomy of folk modules is presented in **Figure 1** (Geary, 2005). The function of these folk systems is to focus behavior on attempts to achieve access to and control of the social, biological, and physical resources that tended to enhance survival or reproductive prospects during human evolution. Achieving control is not an easy task, of course, and if it occurs it is typically without conscious awareness of the corresponding evolved function. The development of friendships is supported by folk-psychological competencies, but does not appear to be guided by a motivation to control the behavior of these people, or at least there is often no explicit desire to do so. Nevertheless, having these relationships provides the social support that is correlated with physical and psychological health and in some contexts mortality risks (e.g., Taylor et al., 2000). These friendships are social resources that can enhance survival (e.g., support during times of social conflict) and reproductive prospects (e.g., a romantic partner) under the types of conditions found in traditional societies and presumably throughout human evolution.

Folk Psychology

The folk-psychological modules represent systems that process information related to the self, other individuals, and group dynamics, respectively. The first set includes awareness of the self as a social being and awareness of one's relationships with other people. Self-awareness is related to the ability to mentally project the self backward in time to recall and relive episodes that are of personal importance and to project oneself forward in time to create a self-centered mental simulation of potential future states that become goals to achieve (Suddendorf and Corballis, 1997). The individual level modules process the forms of information that guide one-on-one social dynamics and foster one-on-one social relationships (Bugental, 2000). The group-level modules enable individuals to break their social world into categories of people, including kin and members of favored in-groups and disfavored out-groups. People also have the unique ability to form in-groups on the basis of ideology, such as nation.

Figure 1 System of evolved modular systems in the domains of folk psychology, folk biology, and folk physics. Adapted from Geary, D.C., 2005. Origin of Mind: Evolution of Brain, Cognition, and General Intelligence. American Psychological Association, Washington, DC, p. 129.

Folk Biology and Physics

The folk-biological modules orient attention toward important features of the biological world, such as movement patterns of potential prey, and support the ability to develop taxonomies of other species and knowledge systems about the behavior, growth, and 'essence' (something akin to their 'spirit') of these species that in traditional societies support hunting and horticulture (Atran, 1998). The folk-physical systems support navigation, the formation of mental representations of physical features of the ecology, the construction of tools, and an implicit understanding of magnitude, number, and time. Some of these competencies, especially the ability to navigate, are similar to those found in other species and thus are not uniquely human (Tomasello and Call, 1997). The ability to construct and use tools, in contrast, far exceeds the competencies found in chimpanzees (*Pan troglodytes*) and other species (Povinelli, 2000).

Heuristics and Attributional Biases

Gigerenzer and colleagues' (Gigerenzer et al., 1999) heuristics represent 'rule of thumb' patterns of behavior that are evoked based on the implicit (below conscious awareness) processing of key ecological or social cues. For instance, in many species of bird, females are attentive and sexually responsive to the bright plumage of males of the same species without an explicit understanding that this coloration signals genetic health or the ability to provision offspring (Hill and McGraw, 2006). Females and their offspring thus benefit from mating with these males, resulting in the evolution of a rule of thumb ('mate with colorful males') heuristic for these species of bird; Simon (1956) referred to these implicit relations as bounded rationality, as illustrated in Figure 2. Many human biases (e.g., preference for symmetric faces in mates) reflect similar implicit heuristics. For humans,

Figure 2 Bounded rationality is a coupling of ecological and social information patterns that occurred regularly during the species' evolutionary history and complementary brain and cognitive systems that have evolved to direct the organisms' attention to and process this information. The coupling can result in automatic behavioral responses that act on the ecological or social information, although people can override these biases and respond based on conscious evaluation of the information. Adapted from Geary, D.C., 2005. Origin of Mind: Evolution of Brain, Cognition, and General Intelligence. American Psychological Association, Washington, DC, p. 173.

heuristics can also include explicit inferential and attributional biases that are integral features of folk knowledge. The attributional biases that favor members of the in-group and derogate members of out-groups are well known (Stephan, 1985) and facilitate coalitional competition (Horowitz, 2001) Kahneman and Tversky's (1982) simulation heuristic involves use of the person schema to mentally simulate and make judgments about how the individual might react in one situation or another. The essence associated with folk biology allows people to make inferences (e.g., during the act of hunting) about the behavior of members of familiar species, as well as about the likely behavior of less familiar but related species (Atran, 1998). Attributions about causality in the physical world have also been studied. Children and adults have, as an example, natural, naive conceptions about motion and other physical phenomena (Clement, 1982).

Evolution and Cognitive Development

Over evolutionary time, the human developmental period has increased from about 11–13 years to 18–20 years (Bogin, 1999). The lengthening of this period comes with a profound risk – death before the age of reproduction – and thus would only evolve if there were benefits that outweighed this risk. Studies of other primates with comparatively long periods of development suggest that an important adaptive benefit is the accompanying ability to refine the physical, social, and cognitive competencies that support survival and reproduction. A long developmental period is found in all social mammals and the length of this period increases with increases in the complexity of the species' social system (Joffe, 1997). These patterns suggest that one critical purpose of childhood is to practice and refine folk-psychological competencies, such as using language to influence the behavior of other people.

Play, social interactions, and exploration of the environment and objects appear to be the mechanisms through which these emerging competencies are practiced and refined during development. Child-initiated social play, exploration, and so forth are intimately linked to cognitive and brain development, in that these activities provide experiences with the social, biological, and physical world. These experiences interact with the inherent but skeletal structure of folk modules and ensure their normal development and adaptation to local conditions. As an example, infants' inherent orientation to human faces will provide the experiences necessary to recognize their parents and to elicit caregiving and investment from these parents. In this view, children are biologically prepared to learn about other people and the biological and physical world, and are inherently motivated to seek out experiences that will facilitate this learning (Greenough et al., 1987; Scarr, 1992). The result is that these folk systems are fine-tuned to the nuances of the social group and ecology in which they live.

Implications for Education

Evolved folk abilities and associated behavioral strategies are sufficient for coping with the environments of our ancestors, but these abilities and strategies are not well suited to all contemporary conditions. This is a result of humans' extraordinary ability to create evolutionarily novel knowledge and competencies; these include reading, writing, and arithmetic (Geary, 2005, 2007). During the last several thousand years the cross-generational accumulation of evolutionarily novel knowledge (e.g., through books) has occurred at such a rapid pace (Richerson and Boyd, 2005) that the attentional and cognitive biases that facilitate the adaptation of folk abilities to local conditions during children's natural activities do not have evolved counterparts to facilitate the learning of secondary abilities to the same degree. The emergence of formal and mandatory schooling is a reflection of this mismatch and is a recent cultural innovation that is designed to better prepare children for living in the evolutionarily novel context, we call modern society.

Much of formal education is 'unnatural' in that what children are expected to learn in school involves tasks never encountered by our ancestors (Geary, 1995; Rozin, 1976). The basic goals of schools and schooling are thus to organize the activities of children so that they acquire competencies, such as the ability to read, and scientific and technical knowledge that lead to ways of understanding the world that differ from evolved heuristics and attributional biases. This is so that they can better function in a wider culture that contains many demands (e.g., need to understand compound interest) that have no evolutionary history (e.g., Geary, 2012b).

Evolution and Academic Development

Geary (1995) referred to language and other folk modules as *biologically primary abilities*, and skills that build upon these primary abilities but are principally cultural inventions, such are reading, as *biologically secondary abilities*. The mechanisms by which evolved systems are adapted to produce secondary competencies include the prefrontal cortex, the attentional and inhibitory control components of working memory, and the problem-solving competencies defined by fluid intelligence, but discussion is beyond the scope of this article (see Geary, 2005). One important point here is that because primary modular systems are inherently modifiable, they can – with sustained effort and practice – be modified or combined in unique ways to create biologically secondary abilities. The second point is that the creation of secondary abilities will require the explicit and effortful representation of the to-be-learned information in working memory, and oftentimes the inhibition of folk heuristics and attributional biases (Geary, 2012b).

The relation between language, a primary ability, and reading, a secondary ability, provides an example. Reading and writing are the principal means through which secondary knowledge has accumulated during the past several thousand years (i.e., through books) and are critical to the acquisition of this knowledge in school. From an evolutionary perspective, reading and writing systems initially emerged from motivation to communicate with and attempt to influence the behavior of other people, and therefore it is not surprising that they engage at least some of the same folk-psychological systems (e.g., Mann, 1984; Rozin, 1976). The following sections illustrate how this form of analysis can be used more generally with an evolutionary educational

psychology approach to academic learning, by placing learning to read and reading comprehension in the context of several folk-psychological domains.

Cognitive Mechanisms

The cognitive predictors of children's reading acquisition, the effectiveness of various types of reading instruction, and sources of individual differences in ease of learning to read support the prediction that many core reading competencies are dependent on language systems (e.g., Bradley and Bryant, 1983; Mann, 1984). The crucial early components include phonemic awareness – explicit awareness of distinct language sounds – and the ability to decode unfamiliar written words into these basic sounds. Decoding requires an *explicit* representation of the sound (e.g., *ba*, *da*, *ka*) in phonological working memory and the association of this sound, as well as blends of sounds, with corresponding visual patterns that are also explicitly represented in working memory (specifically, letters (e.g., *b*, *d*, *k*) and letter combinations, respectively (Bradley and Bryant, 1983)).

Children with a strong explicit awareness of basic language sounds are more skilled than are other children at associating these sounds with the symbol system of the written language and thus learn to read more quickly than other children (Wagner et al., 1994). Unlike natural language learning, the majority of children acquire these competencies most effectively with systematic, organized, and teacher-directed (or parent-directed) explicit instruction on phoneme identification, blending, and word decoding (e.g., Hindson et al., 2005). Skilled reading requires text comprehension, that is, an understanding of the meaning of the composition which in turn is dependent on several component skills; for instance, locating main themes and distinguishing highly relevant from less relevant passages. As with more basic reading skills, many children require explicit instruction in the use of these strategies to aid in text comprehension (Connor et al., 2004).

Another evolution-based prediction is that reading comprehension will be dependent in part on theory of mind and other folk-psychological domains (**Figure 1**), at least for literary stories, poems, dramas, and other genre that involve human relationships (Geary, 2007). Most of these stories involve the recreation of social relationships, more complex patterns of social dynamics, and even elaborate person schema knowledge for main characters.

Brain Mechanisms

The neuroanatomy of language is well known and overlaps considerably with the brain regions that support phonological decoding, reading fluency, and text comprehension (Price and Mechelli, 2005). Price (2000) concluded that passive processing of language sounds occurs in the traditional Wernicke's area (part of the temporal cortex); speech production involves Broca's area and areas that support word articulation (part of the frontal cortex); and, the representations of the meaning of spoken and heard utterances is distributed across the temporal and parietal cortices. Prefrontal working memory areas related to language are engaged when the speaker or listener has to make active decisions about the utterances (Poldrack et al., 1999).

Among other regions, tasks that tap phonological awareness or involve phonological decoding during the act of reading engage Wernicke's and Broca's areas, as do tasks that involve the reading of single words. Word reading also engages areas in the temporal and parietal cortices that support the comprehension of spoken utterances (Price and Mechelli, 2005). Early research on the comprehension of the syntax and the basic meaning of read sentences suggested engagement of the same brain regions that support the production and comprehension of spoken utterances, including Broca's and Wernicke's areas (Just et al., 1996).

These findings are consistent with the view that instruction in school, with reading as an example here, involves the modification of the brain and cognitive systems that support folk abilities in the creation of evolutionarily novel abilities that are culturally relevant. The example here touches only the surface of the complexity of the creation of biologically secondary abilities (for elaboration see Geary, 2005, 2007, 2012b).

Motivation to Learn

One very important implication of the evolutionary perspective is that the motivation to acquire school-taught secondary abilities is based on the requirements of the larger society and not always on the inherent interests of children. Given the recent emergence of near universal schooling in modern societies, there is no reason to believe that the skills that are taught in school are inherently interesting or enjoyable for all children to learn. This does not, however, preclude the self-motivated engagement in some secondary activities. Even though reading is a secondary ability that involves the modification of primary language systems, many children and adults are motivated to read. This motivation, however, is probably driven by the content of what is being read rather than by the process itself. Furthermore, the finding that intellectual curiosity is a basic dimension of human personality suggests that there will be a number of curious individuals who will pursue secondary activities (Berlyne, 1966). The more critical point is that the motivation to engage in the activities that will promote the acquisition of secondary abilities is not likely to be universal (e.g., Larson and Richards, 1998); in fact, curiosity is often fleeting and influenced by current knowledge, interests, and other factors (Loewenstein, 1994).

Traditional studies of achievement motivation include children's understanding of the relation between effort and ability on academic outcomes (Nicholls, 1984); valuation of academic learning in terms of mastery (i.e., motivated desire for a deep understanding of the material) or performance (e.g., standing relative to others) goals (Ames and Archer, 1988; Dweck and Leggett, 1988); academic self-efficacy (e.g., Bandura, 1993); and expectancy of success and attributions regarding the sources of success or failure (e.g., ability vs bad luck) in achieving academic goals (Weiner, 1990; Wigfield and Eccles, 2000). An integration of these models and the corresponding literature within an evolutionary framework is beyond the scope of this article, but I illustrate that such integration can be achieved by considering Bandura's (1997) model of social and cognitive self-efficacy.

"People make causal contributions to their own functioning through mechanisms of personal agency. Among the mechanisms of agency, none is more central or pervasive than people's beliefs about their capabilities to exercise control over their own level of functioning and over events that affect their lives" (Bandura, 1993: p. 118). Self-efficacy is an aspect of this personal agency and at its core is a self-referenced appraisal regarding the likelihood of success in various domains and through these influences, among other things, the pursuit of achievement in these domains and persistence in the face of failure. Bandura emphasizes one's explicit appraisal of efficacy and attributions regarding associated outcomes (e.g., cause of failure). From an evolutionary perspective, these map onto the folk-psychological domains of self-awareness, self-schema, and the ability to explicitly represent associated information in working memory and to problem solving on the basis of this information (see Geary, 2005, 2007).

In other words, Bandura's (1993, 1997) model of self-efficacy is consistent with an evolutionary perspective, but with different points of emphasis regarding children's academic motivations and corresponding self-evaluations. One area of difference is with respect to the prediction of domain-specific and inherent learning and motivational biases associated with folk knowledge and a much weaker motivational bias for evolutionarily novel academic learning such as mathematics. Further, the core of the self-schema is predicted, from an evolutionary perspective, to be referenced in terms of one's standing vis-à-vis peers and, importantly, more so for traits that have an evolutionary history than for culture-specific knowledge and abilities. The former includes physical abilities and attractiveness, social influence, and family status (Geary, 2010). These are predicted to be universal and to have substantial influences on the development of self-schemas and self-evaluations. This is contrasted with culturally specific activities, such as schooling, that are predicted to be important in these cultures but less central to most children's and adolescents' emerging self-schemas and evaluations. In keeping with this view is the finding that self-awareness and the emerging self-schema are embedded in a web of social relationships and that the best predictor of global self-esteem from childhood to adulthood is perceived physical attractiveness (Harter, 1998, 2006) and not, for instance, grades in high school mathematics classes.

From an evolutionary perspective, the valuation of academic achievement and the relation between achievement and self-esteem is predicted to be highly variable across and within cultures, and to be heavily dependent on explicit parental and cultural valuation of associated activities and outcomes (e.g., grades; Stevenson and Stigler, 1992), and heavily influenced by peers' valuation of academic achievement (Harris, 1995). From a social learning perspective (Bandura, 1986), many children will imitate parents and teachers who engage in academic activities (e.g., reading); many will come to focus on these activities because they provide access to culturally valuable resources such as a job and income; and, many will come to enjoy these activities in their own right, developing a mastery orientation (Winner, 2000). Children and adolescents will also develop a sense of academic self-efficacy in cultures with formal schooling. These outcomes also follow from an evolutionary perspective that includes evolved modes of cross-generational knowledge transmission.

One important difference comparing the social learning and evolutionary perspectives is with respect to the specificity of predictions: For instance, with successive grades, academic content will increasingly diverge from its evolved foundation, and thus academic learning is predicted to become more difficult and any motivation to engage in this learning is predicted to decrease; and this is the case (Eccles et al., 1993). Social living also becomes more complex and nuanced as people mature into adulthood, but motivational disengagement from social life is predicted to be far less common than disengagement from academic life. These differences follow logically from an evolutionary perspective, but less readily from a strictly social learning perspective.

If our goal is universal education that encompasses a variety of evolutionarily novel academic domains (e.g., mathematics) and abilities (e.g., phonetic decoding as related to reading), then we cannot assume that an inherent curiosity or motivation to learn will be sufficient for most children and adolescents. Children's and adolescent's explicit valuation of academic learning, the perceived utility of academic skills, and the centrality of self-efficacy in these areas to their overall self-esteem is predicted to be highly dependent on social–cultural valuation of academic competencies, such as explicit rewards for academic achievement (e.g., honor rolls) and valuation of cultural innovators (e.g., Edison). These types of cultural and social supports are critical because the lack of inherent motivation to learn in secondary domains and the difficulty of this learning are also predicted to result in negative attitudes and avoidance (e.g., of mathematics) for some students. In contrast, the child's and adolescent's valuation and perceived efficacy of their physical traits or social relationships are implicit features of their evolved folk psychology and will manifest with or without cultural supports, contrary to current assumptions regarding the source of the focus on these traits (e.g., Harter, 1998).

Implications for Instructional Activities

The disconnect between children's evolved motivational biases and the motivational focus needed to excel in modern academic domains and the gap between primary abilities and secondary abilities that is rapidly accumulating in modern societies is, at first blush, rather discouraging. Our lives and those of our children would be considerably easier, if all children found academic learning as engaging as they find interacting with their peers and as effortless as learning their native language. The value of an evolutionary approach to education is not only to better understand the roots of motivational and learning challenges that children face in modern schools, but also to provide a different perspective on what might be done to facilitate children's engagement of and success in academic learning.

There may be some conditions in which children's social play and discourse can be used to facilitate the acquisition of academic skills. The key may be to capitalize on the fuzzy boundary between the primary and secondary domains during the early years of schooling and children's motivation

to learn culturally important knowledge and to use these to build academic self-efficacy and other beliefs that will help to maintain effort and motivation in school learning in later years. Children's natural interest in novelty and their motivation to learn their culture will get them started but is not likely to maintain long-term academic learning.

Children's evolved biases, such as social play, and their observation of and learning from culturally successful adults result in the automatic and effortless modification of folk systems and the learning of the forms of culturally important activities, such as hunting, that have a long evolutionary history. For these domains and activities, there are corresponding motivational biases that ensure that children engage in the necessary activities. If we assume that children are inherently motivated to learn in secondary domains and learn them as effortlessly as they learn in primary domains, then we risk undervaluing the importance of focus and effort for secondary learning. Without an explicit assumption that learning will require effort, we risk having children assume that school learning will occur effortlessly. When effort is required for learning and children begin to experience failure, they are at risk for making attributions that may undermine their later engagement with school.

In closing, an evolutionary approach to children's learning and motivation in school can explain why learning to read is more difficult for children than learning their native language, among many other primary–secondary contrasts (Geary, 2007, 2012a, 2012b), and why many children are more motivated to socialize with their friends than to learn algebra. This perspective has profound implications for how to design instruction to address these differences between primary and secondary learning and to better understand and address the motivational and attributional (e.g., that learning will require effort) factors that will influence long-term engagement in academic learning.

This article is a revision of the previous edition article by K. Sterelny, volume 21, pp. 14543–14549, © 2001, Elsevier Ltd.

Abstract

Evolutionary approaches to human behavior date back to Charles Darwin, though they were somewhat eclipsed in the first half of the twentieth century. They began to become more prominent, as evolutionary studies of animal behavior matured as a scientific discipline in the middle of the twentieth century. The sociobiological approach prevalent in the 1970s and 1980s has been succeeded by a variety of approaches, including human behavioral ecology, evolutionary psychology, and gene–culture coevolution or dual inheritance theory. This article details the inception, prominent proponents, key features, representative case studies, and major criticisms of each of these three current approaches. It also notes the current trends in the field, toward greater use of computer models and experimental methods in studying human behavioral evolution.

Intellectual Background

The idea that it could be illuminating to take an evolutionary approach to understanding humans – our behaviors as well as our bodies – dates back at least to Charles Darwin. In his concluding remarks to *The Origin of Species*, Darwin predicted that, in the course of future developments of the theory he had just presented, "light will be thrown on the origin of man and his history" (1859: p. 647). Darwin followed up this brief allusion to human evolution in the *Origin* with a far more substantial treatment of the topic several years later in *The Descent of Man* and *The Expression of the Emotions in Man and Animals*. There, he defended what can be called a 'continuity' thesis: "the difference in mind between man and the higher animals, great as it is, certainly is one of degree and not of kind" (1871: p. 151). That is to say, the impressive mental abilities that underlie humans' complex ecological, social, and technological behavior – the abilities to imitate, reason, invent, remember, imagine, and more – do not constitute a deep divide between humans and the rest of the natural world. Rather, Darwin thought, such abilities have precursors in, and gradually evolved out of, more basic capacities found in other animals.

One idea of Darwin's has recently become the focus of renewed interest and debate: Darwin's appeal to group selection in his explanation of human mental and behavioral evolution. In particular, in speaking specifically about the human capacity for morality and its effectiveness in underwriting cooperative and altruistic behavior, Darwin claimed that "a high standard of morality gives but a slight or no advantage to each individual man and his children over the other men of the same tribe [but] an increase in the number of well-endowed men and an advancement in the standard of morality will certainly give an immense advantage to one tribe over another" (1871: p. 157). The key idea here is that the evolution of certain traits that are puzzling in terms of the individual bearer's success can be explained in terms of the advantages those traits provide to the bearer's group. Such group selectionist thinking was influential in evolutionary biology for a long time after Darwin, receiving a comprehensive modern statement in Vero Wynne-Edwards' (1962) work, *Animal Dispersion in Relation to Social Behaviour*. While Darwin's suggestion remains very controversial – though recently revived in contemporary guise by Samuel Bowles and Herbert Gintis (2012) – the puzzle of human cooperation remains very prominent in recent work.

The adoption in the 1960s of the so-called gene's-eye view saw the decline of group selectionist explanations (Williams, 1966; Maynard-Smith, 1964; Dawkins, 1976), though as noted above, the idea has made a return (Sober and Wilson, 1998). To take the gene's-eye view is to consider, in a given set of circumstances, what characteristics a gene would need to have in order to increase its frequency over generational time. The problem this perspective reveals in group-selectionist thinking is that groups of cooperative individuals, for instance, are vulnerable to undermining from within. In such a group, an individual with a gene that led it to take the benefits of others' cooperative behavior while refraining from itself paying the costs of cooperating would do better than its cooperative conspecifics. Over generational time, such individuals would outcompete and come to replace cooperators, and cooperation itself would collapse.

In the 1960s, William Hamilton pioneered an alternative approach to the evolution of social behavior (there were also important other theorists: especially John Maynard-Smith, George Williams, and Robert Trivers). Hamilton saw that genes for cooperative behavior could spread by promoting the success of kin, likely to carry the same genes, even when cooperative behavior imposed a cost on the cooperative agent. These ideas were originally developed to explain the extraordinary levels of cooperation among social insects, but were then extended to other forms of social life, including human social life, in a set of ideas that came to be known as human sociobiology, and that was prominently advocated by E.O Wilson in his *Sociobiology: The New Synthesis* (1975).

As noted above, an important element in this new tool kit was a reconceptualization of the notion of fitness: Hamilton showed that cooperating to help kin may evolve, despite decreasing the helper's 'personal' fitness provided it generates a compensating increases in the helper's 'inclusive fitness' (1964: p. 8). That is to say, if the cost of helping decreases the number of genes the helper contributes to the next generation

in the form of its own offspring by less than the help increases the number of genes (identical by descent to the helper's) passed on by the helper's relatives, then helping makes evolutionary sense. This inequality has come to be known as Hamilton's Rule, and this way of accounting for the evolution of certain kinds of cooperative social behavior, as kin selection.

Not all social behavior involves interactions between kin; humans, in particular, do not typically live in groups composed solely of close kin. Robert Trivers' (1971) theory of reciprocal altruism did much to help explain cooperative behavior outside the family (see also Axelrod, 1984). Trivers realized that such behavior could be fitness-advancing for the helper so long as several conditions were met. First, there must be an asymmetry between the cost and the benefit of helping, with the cost of helping being small compared to the benefit helping confers. Second, there must be the potential for individuals to interact repeatedly and to switch roles (i.e., helper vs. beneficiary). Third, individuals must have the ability to recognize those who have helped them in the past. Fourth and finally, individuals must have a tendency to help those who have helped them in the past and to withhold help from those who have failed to help them. Under these conditions, the immediate cost of helping another individual can be recouped (and more) over time as one's beneficiaries repay one's helpfulness in kind. Cooperation under these conditions can thus work out to a helper's long-term advantage.

Trivers' proposed explanation for apparently fitness sacrificing helpfulness has come to be called 'direct' reciprocity, since it involves pairs of individuals that trade favors with each other. Richard Alexander (1987) extended Trivers' work by suggesting that reciprocity might also be indirect, in which case "the return is expected from someone other than the recipient of the beneficence" (1987: p. 85). Alexander explained the fitness value of reputation, and of the value of investing in having a good reputation. Reciprocity, both direct and indirect, was another important explanatory resource for sociobiologists attempting to explain the evolution of human social behavior. Indirect reciprocity might be especially important in the human case, for it is not clear that Trivers' mechanism scales up to cooperative interactions that depend on more than two agents, for withholding help then becomes a very blunt instrument in response to cooperation failure: it imposes costs on the whole coalition rather than on the specific individuals who fail to cooperate (Sterelny, 2012).

The final chapter of Wilson's (1975) *Sociobiology* was devoted to humans, as was his Pulitzer Prize-winning *On Human Nature* (1978). In these publications, Wilson drew on the resources described above to develop sociobiological explanations for numerous behaviors he took to be human universals, including religious and ritual performance, the creation of art, engaging in trade, making war, and acting ethically.

The specifics of the sociobiologists' claims, and of the critical response to sociobiology, have been covered in great detail elsewhere (Segerstrale, 2000; Laland and Brown, 2002; Kitcher, 1985). More generally: (1) Sociobiology was behavior-oriented: the focus was on particular kinds of behavior, such as those mentioned above, rather than on the psychological mechanisms that generated those behaviors. The guiding assumption was that particular behaviors could be tuned by selection independently of one another, and hence human sociobiology was in increasing tension with the developing cognitive psychology, which saw particular behaviors as the result of interactions among cognitive mechanisms, each of which contributed to many behaviors, in many different contexts. (2) Sociobiology was adaptationist: the guiding aim was to explain its target behaviors as the results of natural selection, that is, as adaptations. (3) Sociobiology was, often, speculative: it had about it the air of just-so storytelling (Kitcher, 1985), with claims about evolution of certain human behaviors resting on appealing, perhaps plausible, but evidentially undersupported suggestions about adaptive advantage. This speculative nature of human sociobiology was particularly significant given that many of its claims were politically loaded, such as claims about homosexuality and territorial violence. (4) Finally, sociobiology was primarily concerned with identifying and explaining human behavioral similarities – the supposed human universals – not with diversity in human behavior.

Changes in Focus

Three current major evolutionary approaches to human behavior are detailed below. All of these approaches can be understood in contrast with – in some cases as reactions to or developments of – sociobiology.

The first approach, human behavioral ecology, represents a shift in focus compared to sociobiology, away from seeking universals and on to understanding diversity. The second, evolutionary psychology, was a self-conscious break with sociobiology for at least some of its practitioners, and contrasts with that earlier approach insofar as it focuses not on behavior itself, but on the psychological mechanisms that underlie and generate behavior. Finally, the third approach detailed below, gene–culture coevolution, represents a move away from sociobiology's gene-centric and adaptationist viewpoint by attempting to integrate cultural with genetic influences on human behavioral evolution, and also by recognizing the potential for cultural forces to lead to maladaptive outcomes over evolutionary time.

Current Knowledge

Human Behavioral Ecology

Behavioral ecologists attempt to understand the adaptive rationale of animal behavior. The discipline emerged in the 1960s and 1970s from the ethology that Tinbergen and Lorenz had established as a valid branch of the biological sciences, by integrating the formal machinery of evolutionary biology with the experimental and field methods of ethology. Human behavioral ecology is the application of those methods to humans. The discipline first appeared in the 1970s, and was pioneered and subsequently developed mostly by anthropologists, such as William Irons, Napoleon Chagnon, Irven DeVore, Kristen Hawkes, and Monique Borgerhoff Mulder.

The first key feature of human behavioral ecology is its emphasis on humans' capacity for adaptive behavioral plasticity in the face of environmental variation. Human behavioral ecologists make what has been dubbed the 'phenotypic gambit'

(Grafen, 1984), essentially betting that genetic constraints on human behavior are sufficiently loose that humans can flexibly adjust their behavior to maximize reproductive success across a wide range of different environments. Human behavioral ecologists' models assume that humans can recognize and assess, reasonably accurately, the options available to them, and that they prefer options (more food, more sex, safety, friendship) which as a matter of fact typically promote their fitness interests; subjective utility and objective interests mostly match. But their models typically leave these cognitive assumptions tacit: they explicitly focus on identifying the costs and benefits of different choices.

The second key feature of human behavioral ecology is its use of formal models. Optimality models in particular are central to this approach to human behavioral evolution. The process by which such models are employed is as follows. First, model construction, in which the behavior of interest is defined, and its costs and benefits, along with the relevant environmental parameters, are specified. The purpose of the model is to identify the behaviors that maximize fitness under the given environmental conditions. Next comes data collection. Here, the human behavioral ecologist operates much like a traditional anthropologist, directly observing members of a subject population, conducting interviews, and drawing on historical material, all with the aim of discovering how the members of that population actually behave in their environment. Finally, model testing occurs when the predictions of the optimality model are compared to the actual behaviors to determine whether the real-world people are behaving so as to maximize their fitness.

The particular model that a human behavioral ecologist uses will depend on the target behavior of interest. Models commonly used include optimal foraging theory, life history theory, sex allocation theory, and the polygyny threshold model.

Eric Alden Smith's (1985) research on the Inuit is an example of the use of optimal foraging theory to investigate human foraging practices. Optimal foraging models seek to quantify the costs and benefits of various foraging decisions – about prey choice, time allocation, patch choice, movement, and group formation, among others – in order to assign to the various possible foraging strategies a payoff that can serve as an adequate fitness proxy, such as net rate of energy capture. The guiding assumption is that foragers will act in ways that maximize this measure. Smith's model predicted that optimal group size for hunting geese was one, while optimal group size for hunting seals was three.

The Inuit did indeed hunt geese alone, but when hunting seals most often formed groups of four and sometimes as many as eight – far from optimal according to the model. Smith interestingly interpreted his results as partial confirmation for the view that the Inuit tailored their foraging behavior in ways that maximized their fitness, and also as an indication of the operation of previously unconsidered constraints on Inuit foraging behavior. In particular, Smith thought social factors, such as the costs of excluding individuals from group hunts, constrained optimization for some forms of foraging. This case study thus shows both how human behavioral ecology's guiding assumption of human adaptive behavioral flexibility, together with the formal modeling methods employed, can find confirmation in actual observed human behaviors, and also how even failures can be fruitful in suggesting refinements to models for future research.

Other examples of human behavioral ecology in action include the use of sex allocation theory and the polygyny threshold model to assess the adaptiveness of mating practices and patterns of parental investment in offspring. For example, Rebecca Bliege Bird (2007) has developed an elegant model to explain turtle hunting among the Meriam in North East Australia: male turtle hunting is (she argues) a signal of social and physical skill rather than mere resource acquisition.

Human behavioral ecology is not without its critics. Donald Symons (1990) criticized human behavioral ecologists' focus on the adaptiveness of behaviors – whether the behaviors were currently fitness enhancing – rather than on whether the behaviors were adaptations, that is, the products of a history of natural selection. Being adaptive and being an adaptation can come apart: not all currently adaptive traits are adaptations, and not all adaptations are currently adaptive. So, showing that certain behaviors are adaptive does not show that they are adaptations. There are two issues lurking here. First, how, exactly, does showing (say) that male turtle hunting among the Meriam is adaptive *explain* that form of social behavior? Given that behaviors themselves are not the result of natural selection, how does the adaptiveness of turtle hunting stabilize that social practice? Second, the fact that being adaptive and being an adaptation can come apart calls into question the phenotypic gambit. If human selective history and the adaptations it has shaped place significant constraints on human behavioral flexibility, then people now may sometimes – perhaps often – fail to behave in ways that maximize fitness. After all, there seem to be plenty of prima facie examples of biologically maladaptive behavior; for example, much of the western world prefers wealth to children. If true, this would undermine the guiding assumption of human behavioral ecology. Symons and Tooby are representatives of an approach to human behavioral evolution – evolutionary psychology – on which this possibility is thought actual. This approach is detailed below.

Evolutionary Psychology

Evolutionary psychology was conceived in the 1980s and championed by anthropologist John Tooby alongside Leda Cosmides, a psychologist. Cosmides and Tooby distinguished their approach to understanding human evolution from that of Wilson and the sociobiologists, and from the human behavioral ecologists, by focusing on psychological mechanisms for producing behavior rather than directly on behaviors themselves. Cosmides and Tooby considered the focus on behavior a "conceptual 'wrong turn'" (1987: p. 278), and one they aimed to correct. They were joined in this endeavor by the likes of Donald Symons, David Buss, Margo Wilson, Martin Daly, Steven Pinker and Dan Sperber.

The key features of evolutionary psychology are as follows. First, the approach is explicitly adaptationist, in that it supposes that the psychological mechanisms underlying human behavior are adaptations. Secondly, it stresses the fact that human psychological mechanisms for generating behavior were designed by selection to solve recurrent adaptive problems in

the evolutionary environment of our ancestors – the environment of evolutionary adaptation, or EEA – and hence, in slogan form, our modern skulls house Stone Age minds. This form of evolutionary psychology is a version of classical, nativist cognitive psychology: these psychological mechanisms are computational, information-processing mechanisms, and they are designed and prewired to solve specific, crucial, recurrent informational challenges faced by Pleistocene foragers. Methodologically, evolutionary psychologists first employ functional analysis to 'reverse engineer' the mind, meaning that they hypothesize adaptive problems faced in our evolutionary past, postulate solutions to those problems, then conduct studies much like nonevolutionary psychologists to determine whether the postulated mental mechanisms actually exist. The method of reverse engineering the mind leads evolutionary psychologists to a core commitment of their approach, namely, the 'massive modularity' thesis, according to which the human mind is made up of a large collection of individual mechanisms, 'modules', each designed to solve a distinct adaptive problem. Since they are dedicated to specific tasks, these mechanisms are said to be domain-specific. Finally, evolutionary psychologists claim that this suite of modules constitutes an evolved and universal human nature.

Leda Cosmides' (1989) work investigating how people perform across different versions of the Wason Selection Task provides a representative example of evolutionary psychology in action. Cosmides began by positing an adaptive problem important in human evolutionary history, namely, that of processing social information, and in particular detecting violations of social rules or cheating in social exchanges. She hypothesized that humans have evolved a mental module specialized for solving this adaptive problem.

To test this hypothesis, Cosmides had subjects attempt different versions of the Wason Selection task. In this task, subjects are told a conditional rule of the form 'if P then Q' and asked to determine when this rule may have been violated. Subjects receive information in the form of four cards. Each card is double-sided, one side stating whether the antecedent of the conditional is true or false (i.e., stating either P or not-P), the other side stating whether the consequent is true or false (i.e., stating either Q or not-Q). The subjects' information is incomplete, though; subjects can see only one side of each card. The task is to identify which cards must be turned over in order to determine whether the situation the card represents constitutes a violation of the rule. Logically, only a 'P and not-Q' combination can falsify the conditional rule, hence, the correct choice in the task is to turn over the P card (to see if it has a not-Q on the reverse) and the not-Q card (to check for a P).

When given nonsocial versions of the task, subjects performed poorly – only about 25% made the logically correct card choices – but, when the rule in question was a social rule, such as for instance "if a person is drinking alcohol, then s/he must be over 21," performance jumped markedly, with roughly 75% of subjects choosing to turn over the logically correct cards (in this case, the 'drinking beer' and 'under 21' cards). Cosmides interpreted this pattern of results as support for her hypothesis that humans have mental mechanisms specialized for detecting cheating and violation of social rules.

Other examples of evolutionary psychology in action include comparisons of male vs female mate preferences (Buss, 1989), studies of patterns of child abuse by step as compared to birth parents (Daly and Wilson 1999), and studies of the evolution of rape (Thornhill and Palmer 2000).

Many criticisms have been leveled at evolutionary psychology. One challenge comes in the form of attempts to explain the evolutionary psychologists' own data in ways that do not confirm their hypotheses. For instance, even some researchers who fit neatly enough into the evolutionary psychologists' own camp disputed the Wason selection task findings and interpretation (Sperber and Wilson, 1986). More recently, a prominent example of this kind of criticism is the work of David Buller, who in *Adapting Minds* (2005) takes on evolutionary psychologists case-by-case and offers alternative explanations for the data reported.

To take a specific example, evolutionary psychologists claim that females, more than males, should value high-status mates because such mates are more capable of providing resources during childbearing and -raising (important adaptive problems to be sure). Evolutionary psychologists such as David Buss (1989, 2005) offer data supposedly showing sex differences in mate preference, with females showing greater preference for high-status mates, and claim that these data reflect different evolved solutions to the different adaptive problems facing men and women in this arena. Buller considers the evolutionary psychologists' data and argues that an alternative explanation, namely, assortative mating by status, better explains that data than does the evolutionary psychologists' own hypothesis about evolved sex differences in preferences for status (Buller, 2005). Along similar lines, Garth Fletcher points out that while on average there are some gendered differences in human mate preferences, there is an enormous amount of overlap: men and women in general are looking for very similar virtues in their partners, and the overall message is one of similarity rather than differences (Fletcher et al., 2012). This kind of empirical engagement with evolutionary psychology remains ongoing.

There are more theoretical, global objections. One focuses on evolutionary psychology's picture of the EEA. A relatively easily dismissed version of this objection charges evolutionary psychologists with relying on a naive stereotype of an African savannah; some evolutionary psychologists simply deny that they, at least, were ever so naive (Tooby and Cosmides, 1990). A more trenchant version has it that, according to our best current knowledge, ancestral environments were too variable across time and space for the EEA concept to play the role it is supposed to in evolutionary psychological research. Crucially, part of the variability is due to humans' own role in creating their selective environments: we are not just passive subjects of selection, but active 'niche constructors' (Odling-Smee et al., 1996; Sterelny, 2012), meaning that at least some of the adaptive problems our ancestors faced were not stable but fluid, the results of an evolutionary 'arms race'. Under such circumstances, it may not be possible for selection to design enduring solutions in the form of special-purpose mental modules.

Evolutionary psychologists' 'massive modularity' thesis has often come under critical fire. To the claim that there is not enough time or information available during individual development for a person to learn on their own, how to solve the myriad adaptive problems life poses, it has been said that

socially scaffolded learning – epistemic niche construction – can explain humans' success at solving complex problems (Sterelny, 2012). This view is supported by the fact that humans now live, and act successfully, in social, economic, political, and physical environments vastly different from those of only 10 000 years ago, and our capacity to act successfully in these environments cannot be explained by appeal to innate, evolved modules that guide our responses to the challenges of mass society.

A common concern underlying the previous two objections is that evolutionary psychologists underestimate the extent to which social learning and cultural transmission have mattered in human evolution, and the extent to which human cognitive development depends on environmental shaping as well as genetic endowment (Heyes, 2012). The approach detailed below, gene–culture coevolution, addresses that worry.

Gene–Culture Coevolution

Sociologists see culture as a powerful shaper of human behavior. Sociobiologists by contrast suppose culture to be a relatively weak shaper of human behavior. Between these extremes, most researchers agree that both genetic and cultural influences matter in human evolution; the interesting controversy concerns the relative importance of each, and how to represent and model their interaction. Gene–culture coevolution, also known as dual inheritance theory, is the attempt to specify and quantify how genes and culture interact. The goal of this approach is to understand how cultural changes can affect genetic evolution, and how genetic changes can affect cultural evolution.

Two of the earliest proponents of this approach were E.O. Wilson and his collaborator Charles Lumsden (1981), however, their specific approach failed to take off. Another pair of contemporary researchers were also developing a gene–culture coevolutionary approach. The geneticists Marcus Feldman and Luca Cavalli-Sforza (1976) presented a model of trait evolution that integrated genetic and cultural inheritance systems, and followed this up with a book-length treatment, *Cultural Transmission and Evolution* (1981). Another very fruitful collaboration also began in this period, between anthropologists Robert Boyd and Peter Richerson (1985). They, their students and their collaborators have built an impressive research tradition, in partial overlap with human behavioral ecology. They use an impressive set of formal tools, drawing on models from population genetics and building those into transmission rules for cultural inheritance.

One key feature of the gene–culture coevolution approach is the recognition that humans reliably inherit information through two channels. One channel is genetic: we inherit information via transmission of DNA. The other is cultural. 'Culture' in this context can be ideological, consisting of information, or behavioral, consisting of skills, or even material, consisting of made objects such as tools. We inherit cultural elements via social transmission, through processes such as learning and imitation. There are a variety of directions in which social transmission can occur. One is, like genetic transmission, vertical, meaning from parents to offspring. Unlike genetic transmission (in humans), however, cultural transmission can also be oblique, from a member of a parental generation to a member of the offspring generation, or horizontal, between individuals within a single generation. In part because humans inherit cultural information from sources other than their parents, gene–culture coevolution can sometimes lead to maladaptive outcomes. Gene–culture coevolution can explain why things can go wrong, not just why they can go right.

Michael Tomasello, primatologist and developmental psychologist, has emphasized the fact that human informational inheritance is cumulative: humans inherit cultural information, transmit it, but sometimes with additions and improvements. The great apes are good enough at social learning to receive information from the previous generation, but they do not reliably add to it (Tomasello, 1999). In his view, the transition to accumulating culture was a watershed change in hominin evolution: humans have been genetically selected to learn culturally; there is mutual influence between these channels of inheritance; and as a consequence cultural conditions are hugely important in human evolutionary history (for more on this, see Shennan, 2003; Jablonka and Lamb, 2005; Whiten et al., 2011; Sterelny, 2012).

Research on dairy farming and lactose tolerance provides a good demonstration of the gene–culture coevolutionary approach. The relevant background information to this research is that there is variation worldwide across adult humans in the ability to digest dairy products such as milk. Some people can digest dairy products, in virtue of possessing a certain allele that governs the activity level of the enzyme lactase, which breaks down lactose. Other people – in fact, worldwide, most people – lack the necessary allele, do not produce sufficient lactase, and are made ill by consumption of dairy products. Moreover, possession of the allele for lactose tolerance is far more common in populations with a history of dairy farming than in populations without dairy traditions.

Feldman and Cavalli-Sforza (1989) developed a model of the evolution of lactose tolerance in which both genetic and cultural variation and transmission were included. In the model, lactose tolerance was under the control of a single gene, and the question was under which circumstances that lactose absorption allele would achieve high frequency in the model population. Interestingly, although, the ability to absorb lactose confers a fitness advantage when dairy products are available, the mere presence of dairy farming and the subsequent action of natural selection alone was not sufficient to drive the absorption allele to high frequency. Feldman and Cavalli-Sforza found that the evolution of lactose tolerance depended also, and critically, on cultural transmission. In particular, it must be the case that dairy consumers' offspring were very likely to also become dairy consumers. That is, there must be strong vertical transmission of the cultural trait of being a dairy consumer. In the model, natural and cultural selection acting in concert were required to drive the absorption allele to high frequency. Differences in the strength of cultural transmission of the practice of consuming dairy products may thus explain genetic variation in lactose tolerance across populations.

While the general approach taken by gene–culture coevolution researchers is promising, there are still very few empirically well worked out examples of this approach in

action. This dearth is partly due to a deficit of empirical knowledge, of how to distinguish, count, and track changing frequencies of cultural variants. It is also partly due to the formidable technical challenges of constructing adequate models of gene–culture coevolutionary target systems. One central challenge here is determining the extent to which cultural transmission and selection of cultural variants is a genuinely Darwinian process (Godfrey-Smith, 2009). Dan Sperber has long been skeptical, doubting that cultural learning typically has either the fidelity or chainlike character of true biological inheritance; he suggests that much social learning is diffuse, with subjects gaining a particular skill over many interactions from many sources (Sperber, 1996). Perhaps most significantly, there is currently a lack of integration between gene–culture coevolution and other relevant disciplines, such as paleoanthropology, as a consequence gene–culture coevolution ideas have not been much tested against the known historical record of hominin evolution. In this respect, though, there has been improvement, and the move toward greater integration is an emerging, and encouraging, trend.

Current and Emerging Trends

The increasing use of computer models and of experimental methods are two current and promising trends in the study of human behavioral evolution.

The use of computer models in this field is not new. It traces back at least to early sociobiology: John Maynard-Smith and George Price used game theory to model and understand animal conflict (1973), and Robert Axelrod (1984) held a simulated tournament between various behavioral strategies in the Prisoner's Dilemma. Recently, though, the use of models has been more extensive, and the models themselves more complex. A key figure in this respect is philosopher Brian Skyrms, whose books *The Evolution of the Social Contract* (1996), *The Stag Hunt and the Evolution of Social Structure* (2004), and *Signals* (2010) all apply sophisticated modeling techniques to understanding the evolution of human cooperation and communication, but there have been important contributions from evolutionary biology, human behavioral ecology, gene–culture coevolutionary theory, and evolutionary economics. Skyrms' approach is distinguished by the simplicity and generality of the basic models, the elegance through which these are elaborated, and his ability to situate his models in the context of broad debates both within philosophy and the empirical disciplines.

The key features of this approach are the use of evolutionary game theory and of mathematical models and computer simulation. One first specifies the various behavioral strategies to be assessed, for instance, a set of moves to be made in a cooperative game. Importantly, the 'agents' so modeled can be 'dumb', that is, they need to only behave and need not calculate or strategize. One must also specify the results of interactions between strategies (the 'pay offs'), the starting population composition (how many of each type of strategic agent are initially present), and likelihood of various types of agents encountering others (the degree of assortative interaction, if any). Then, simulations are run using replicator dynamics to see how the population changes over generations as a result of the differential success of the various strategies; doing this many times shows how the population is likely to evolve over time, in terms of both its trajectory and its final state.

This approach has been applied by Skyrms himself to understanding the evolution of fairness – in particular the human tendency to divide windfall resources roughly equally – and of honest and informative signaling. The extension of this approach to new phenomena is an ongoing and potentially very fruitful endeavor. Philosophically, there is a great deal of interest in the use of models as evidence and, relatedly, the relationship between models and the real-world systems they are meant to help us understand. The simplicity of the models makes the approach tractable and comprehensible, but it increases the gap between model and target systems (Weisberg, 2013).

Another recent and worthwhile development is the use of experimental methods. For example, experimental economics examines people's tendencies to divide resources fairly or unfairly, generously or selfishly, to reward fairness and generosity, and to punish unfairness and selfishness, across a range of carefully controlled conditions. One of the experimental economist's basic tools is the so-called money game and its many variants (Davis and Holt, 1992). In the Dictator game, one subject (the dictator) must decide how to allocate a sum of money between themselves and a partner (the receiver), who has no option but to accept the dictated split, even if the dictator chooses to keep the whole sum. In the Ultimatum game, one subject (the proposer) must propose a way of dividing a sum of money with their partner (the responder), who can either accept the offer (in which case proposer and responder share the money as proposed) or reject the offer (in which case neither proposer nor responder gets anything). In the Public Goods game, several subjects must individually decide whether to contribute their own resources to a common pool that will be multiplied by some factor then divided equally among all of the players.

A landmark study exemplifying this approach is that by Joseph Henrich et al. (2005), who collected cross-cultural data on money game play. Norms of fair division and contribution were found to vary significantly at the cultural group level, and this variation to be substantially explained by variation in different groups' socioeconomic histories and current structures. Other work in this relatively new tradition includes that by Ernst Fehr, Simon Gachter, Urs Fischbacher, and Samuel Bowles.

Evolutionary Demography: A Darwinian Renaissance in Demography

Rebecca Sear, London School of Hygiene and Tropical Medicine, London, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Demography and evolutionary biology have a long history: Darwin was famously influenced by Malthus when developing his ideas on natural selection. The two disciplines remained closely associated throughout the early twentieth century. They disassociated after World War II, but in recent decades lines of communication between the disciplines have opened again. Initiatives from both evolutionary scientists and demographers have resulted in some genuinely interdisciplinary work, and evolutionary research is increasingly being published in demography journals and presented at demography conferences. This article will briefly survey the history of interaction between the disciplines and suggest a Darwinian renaissance in demography is underway.

Introduction

Demography is integral to evolutionary biology, given the latter's interest in reproductive success, a composite of survival and reproduction. But evolutionary biology has not always been integral to demography: demography currently considers itself a social science and few modern demographers have training in biology. This is despite the close association of the two disciplines at their inception. This article will outline the relationship between the two disciplines and attempt to demonstrate that, even though the two disciplines diverged during the middle decades of the twentieth century, a Darwinian renaissance is now underway in demography. That a resurgence of interest in evolutionary ideas is seen in demography, more so perhaps than most other social sciences, is no doubt due to a number of factors which ease communication between the two disciplines, including demography's empirical, quantitative basis. Most important, however, is likely to be acknowledgment from both disciplines that the other can be useful in their own endeavors. Many demographers have lamented that demography is a 'discipline without a theory,' leading some to turn to evolutionary theory to help fill this gap. Similarly, some evolutionary scientists have recognized the need to engage with the expertise of demographers; some have even argued that all evolutionary biologists should be demographers (Metcalf and Pavard, in their 2007 paper titled "Why evolutionary biologists should be demographers"). Demography has been described as "sex, death and passion wrapped in indicators" (van den Brekel, cited in Coleman, 2000, p. 27) but, when it comes to at least some of the human evolutionary sciences, there has been a tendency to focus too much on the sex and passion without enough emphasis on the indicators. Evolutionists could therefore learn much from one of demography's great strengths, which is its focus on high-quality data collection and methods, including accurate description before explanatory models are tested.

Darwin, Wallace, and Malthus

Initially, the two fields of evolutionary biology and demography were closely associated. Darwin was famously influenced by one of the earliest writers on population issues, Thomas Robert Malthus, as he developed his ideas on natural selection – the mechanism of evolution – while writing *On the Origin of Species by Means of Natural Selection, or the Preservation of Favoured Races in the Struggle for Life* (first published in 1859). Darwin writes in his autobiography (1876, p. 120):

> In October 1838, that is, fifteen months after I had begun my systematic inquiry, I happened to read for amusement Malthus on Population, and being well prepared to appreciate the struggle for existence which everywhere goes on from long-continued observation of the habits of animals and plants, it at once struck me that under these circumstances favourable variations would tend to be preserved, and unfavourable ones to be destroyed. The results of this would be the formation of a new species. Here, then I had at last got a theory by which to work.

Darwin is referring to Malthus' 1798 work *An Essay on the Principle of Population*, a popular work which expounded Malthus' somewhat pessimistic view that human populations had an inevitable tendency to outgrow their resource base, written as a reaction to the Panglossian spirit which prevailed at the time that human society had never had it better. Malthus, in contrast to this optimism, believed that human society was doomed to perpetual misery because of the disparity between the rate of increase of human populations and that of their food resources. Given, he argued, that food production can only grow, at best, arithmetically $(2 + 2 + 2\ldots)$ but that human population can grow geometrically $(2 + 4 + 16 + 32\ldots)$ then human populations will inevitably grow faster than food production, leading to a never-ending cycle of rapid population growth being brought back into line with resources by the 'positive checks' of famine, war, and disease:

> The power of population is so superior to the power of the earth to produce subsistence for man, that premature death must in some shape or other visit the human race. The vices of mankind are active and able ministers of depopulation. They are the precursors in the great army of destruction, and often finish the dreadful work themselves. But should they fail in this war of extermination, sickly seasons, epidemics, pestilence, and plague advance in terrific array, and sweep off their thousands and tens of thousands. Should success be still incomplete, gigantic inevitable famine stalks in the rear, and with one mighty blow levels the population with the food of the world
>
> p. 126

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81057-0

Malthus' purple prose undoubtedly had a part to play in the popularity of his essay, which was so well received that it was reprinted in six editions, one of which Darwin came across several decades after the first edition (the 'vices of mankind' that Malthus writes about, incidentally, are contraception and abortion, of which Malthus, as a clergyman, strongly disapproved). Alfred Russell Wallace, too, read Malthus, and was equally stimulated by his arguments about the carrying capacity of environments. From Wallace's acceptance speech on receiving the Darwin–Wallace Medal in 1908:

> Finally, both Darwin and myself, at the critical period when our minds were freshly stored with a considerable body of personal observation and reflection bearing upon the problem to be solved, had our attention directed to the system of positive checks as expounded by Malthus in his Principles of Population. The effect of this was analogous to that of friction upon the specially-prepared match, producing that flash of insight which led us immediately to the simple but universal law of the survival of the fittest, as the long-sought effective cause of the continuous modification and adaptation of living things.
>
> p. 9

Curiously, both Darwin and Malthus practiced what they preached in their own reproductive lives. Malthus, to foreshadow the discipline of demography to come, took a policy-oriented view and recommended that the dangers of unchecked population growth should be restrained through the mechanisms of late marriage and sexual abstinence (the title of the second edition of his essay was *An Essay on the Principle of Population: or a View of its Past and Present Effects on Human Happiness; with an enquiry into our Prospects respecting the Future Removal or Mitigation of the Evils which it occasions* demonstrating clearly both his interests in the practical applications of his work and a penchant for even longer book titles than Darwin). Malthus only had three children himself and has no living descendants today. Darwin, proponent of the individual-level perspective that natural selection preserves those 'favored' in the struggle for life, had 10 children and now has more than 100 currently living descendants. Wallace, more moderately, had three children and now has a handful of living descendants.

Evolutionary Biology and Demography in the Early Twentieth Century

Evolutionary biology and demography continued to develop in close association throughout the early twentieth century. Prominent figures during this period moved freely between these disciplines. Alfred Lotka, for example, a mathematician well known in evolutionary biology for his models of population biology (the Euler–Lotka and Lotka–Volterra equations are still widely used), also served as an officer of both the *Population Association of America (PAA)* and the *International Union for the Scientific Study of Population Problems* (*IUSSPP*, which later dropped the second P to become the *IUSSP*, now the largest international population organization). Raymond Pearl, a biologist who also worked on population problems, was involved in founding the biology journals *Quarterly Review of Biology* and *Human Biology* but also the demography associations *PAA* and *IUSSPP*. He is perhaps most well-known for some demographic work, particularly that on mortality and longevity, demonstrating in the 1920s, for example, an association between moderate alcohol consumption and long life.

Practitioners of both disciplines were also closely associated in the eugenics movement, aimed at encouraging the reproduction of those deemed to have desirable attributes and discouraging those deemed undesirable, which reached its peak during this period. Eugenics was promoted by some biologists who saw 'social Darwinism' as an obvious extension of Darwin's theories of evolution and a way to improve the human species (and was devised, incidentally, by Darwin's cousin, Francis Galton). Many prominent population activists, such as the pioneers of the birth control movement in the US and UK respectively, Margaret Sanger and Marie Stopes, were also proponents of eugenics. Stopes was such an ardent eugenicist, she supposedly cut her son out of her will when he married a short-sighted woman, arguing that his children may inherit the defect of myopia (Connelly, 2008). In the UK, the Eugenics Society was involved in the foundation of the Population Investigation Committee, a charity still based at the London School of Economics, which publishes one of the major, and eminently respectable, demographic journals, *Population Studies*.

Divergence after World War II

The two disciplines diverged after World War II, however. The eugenics movement may have been partly responsible for this cleavage. The postwar backlash against eugenics resulting from the explicitly eugenicist aims of Nazi Germany, as well as other human rights abuses linked to the eugenics movement, led to the social sciences striving hard to dissociate themselves from the linkage of biological theories to human affairs. In subsequent decades, the social sciences largely (and often vehemently) denied any role for biology in human behavior and biologists themselves steered clear of engaging with the social sciences. Demography became firmly situated within the social, and not the biological, sciences. In the United States today, for example, demography units are often situated within sociology departments. As a result of this divergence, many demographers have been raised in a social science tradition that views biological explanations of any human behavior with considerable wariness. As the demographer Richard Udry (1999, p. 911) puts it: "Our shared disciplinary [social science] immune systems recognize biological explanation of behavior as an infection, and reject it."

The reasons for this repositioning may not have been entirely political, however. The rapid demographic changes that took place during the twentieth century led many to the conclusion that demography must be more influenced by social factors than biology, since genetic change could not take place so rapidly. An additional factor may have been the very applied nature of demography in the post-World War II period. Much demographic data collection and analysis was focused on describing mortality and fertility levels and their determinants, so that policy could be directed at reducing mortality and fertility rates where they were still high. Arguably, such

applied science, at least in the early stages of mortality and fertility reduction, has relatively little need of theory, as substantial success can be achieved in, for example, reducing child mortality rates in low-income countries, in the absence of any overarching theoretical framework.

Whatever the reasons for the divergence of demography and biology, demography has now effectively shaken off the specter of eugenics, which biology has still not succeeded in doing. This is perhaps a little unfair given that demography was involved quite explicitly in promoting population control in the decades after World War II in the interests of curbing global population growth, in some cases at least with aims which skirted dangerously close to eugenics (see Matthew Connelly's 2008 history of the population control movement 'Fatal Misconception,' which was reviewed by journalist Fred Pearce as "…an investigative narrative of how individuals, NGOs, governments, and UN agencies colluded over decades to sideline the human rights of hundreds of millions of the world's poorest citizens"; New Scientist, 24 May 2008). Those applying an evolutionary perspective to human behavior in recent decades have in contrast taken care to emphasize the errors in eugenicist science and have been much less keen to engage in policy. Demography has since had its own debates about the controversial population control movement (the well-respected demography journal *Population and Development Review* published three highly critical book reviews of Fatal Misconception, including one by prominent demographer and recent president of the *IUSSP*, John Cleland), and now population policies typically have an explicit human rights, rather than population control, agenda. But it is still perhaps ironic that the social science community tends to regard demography as a respectable social science, whereas the application of evolutionary biology to human behavior is not yet wholly accepted as a reputable endeavor.

Renaissance

This postwar split led to several decades of nonfraternization between demography and evolutionary biology, but the rapprochement of the disciplines does now seem to be well underway. After a period of biologists' relative lack of interest in the social sciences, the 1970s saw the emergence of sociobiology – the application of evolutionary theory to social behavior – which stemmed from the work of (nonhuman) animal ethologists in the 1950s and 1960s (Segerstralle, 2001). E.O. Wilson controversially applied this approach to human behavior in the final chapter of his textbook on *Sociobiology: The New Synthesis* (published in 1975). Despite the protests of many within the social science community that this would inevitably lead to a second round of eugenics, the application of evolutionary theory to the human sciences has developed into a thriving and diverse field. While evolutionary psychologists have perhaps become numerically the most dominant of the evolutionary social scientists, there is also a successful discipline of evolutionary anthropology, as well as the integration of evolutionary theory into many other aspects of the human sciences, such as a movement to establish a field of evolutionary medicine.

The resurgence in enthusiasm for combining demography and evolutionary ideas began in the 1980s with a number of meetings aimed at bringing together biologists and demographers. Initially, the focus was on mortality, with workshops on 'Population & biology' in 1981, 'Upper limits to human life span' in 1987, 'Convergent issues in genetics and demography' in 1988, 'Biodemography of longevity' in 1991, and 'Life span: evolutionary, ecological and demographic perspectives' in 2001, though there was also a workshop on 'Biodemography of fertility and family behaviour' in 2002. These workshops have resulted in some exciting advances being made in evolutionary demography during the last few decades, as well as the increasingly frequent appearance of evolutionary ideas at population conferences. All the major population conferences, including the *IUSSP*, *PAA*, *European Association for Population Studies*, and the *British Society for Population Studies*, have now held sessions explicitly devoted to evolutionary demography. Short courses to train students in evolutionary demography have also now been held at the *International School for Demography* in Rostock, Germany, and at Stanford University. Labs in evolutionary demography, led by the Evolutionary Biodemography lab at The *Max Planck Institute for Demographic Research* in Rostock, Germany, are beginning to appear in the United States and Europe. What may be the first tenure-track position in human evolutionary demography was advertised in 2010 at Yale. Finally, and perhaps most notably, an Evolutionary Demography Society (http://www.evodemos.org/default.htm) was established in 2013, which held its first conference in October 2013.

Quantifying the Darwinian Renaissance in Demography?

As both demography and evolutionary biology are empirical disciplines, demographers and evolutionary biologists presumably require empirical evidence that a Darwinian renaissance may be underway. In order to provide some very crude evidence, I have attempted to determine whether biological terms may be increasing in frequency in demography journals over time. To do this, I analyzed the number of times the terms 'evolutionary' and 'biology' appeared in three top demography journals (*Demography*, *Population Studies*, and *Population and Development Review*) over the last few decades, using the jstor database. This database allows a count of the number of times a word appears in these journals within a certain time range (I restricted the analysis to search the full text of research articles only). The number of articles (and therefore the total number of words) published has also increased considerably in these journals over this time period, so to control for this I constructed a faux 'rate' for the appearance of each of these terms by dividing the number of times the term of interest was mentioned by the number of times the word 'population' appeared: making the assumption that the relative frequency of the term 'population' would have remained constant over time. For comparison, I performed the same calculations for the social science terms 'anthropology' and 'psychology.'

Figure 1 shows the absolute increase in the 'rate' of use for each term by decade in the jstor database (*Population* studies appear in jstor since 1947, *Demography* since 1964, and *PDR*

Figure 1 Frequency of terms in three demography journals over time.

since 1975; the analysis was only possible up to 2010 since the jstor database does not include the most recent issues of journals). This figure shows the frequency of all terms has increased relative to the term population over this time period, indicating that demography is becoming more diverse in the disciplines it interacts with. But there are differences in how frequently the different terms are mentioned, and how rapidly these rates have increased over time. 'Biology' is the most widely used term overall, perhaps suggesting that biology and demography have always been somewhat linked, and has increased substantially over time. 'Evolutionary' has seen a much larger increase over time, however. Initially, it was seen very infrequently in these journals, but showed the largest increase over time to become as common as the social science terms included. 'Anthropology' has steadily increased over time, perhaps reflecting the emergence of the field of anthropological demography. 'Psychology' showed little increase until the last decade, which may correspond to a relative lack of interest from demographers in psychology until very recently – perhaps, suggesting the emergence of a very new field of psychological demography.

Why Did the Renaissance Occur?

The reasons for this Darwinian Renaissance are undoubtedly many. The similarity in subject matter of evolutionary biology and demography – resulting from both fields being interested in fertility and mortality – is clearly very important. As the most biological of the social sciences, demography is likely to be rather more open to biological thinking than other social sciences. Demography is also a strongly empirical and largely quantitative discipline, and has not, therefore, been diverted into the cul-de-sac of postmodernism as have so many of the other social sciences. The demographer David Coleman (2000, p. 32) goes as far to say: "Demography without numbers is a bland form of social or historical waffle." Developments in genetics and physiology mean that it is increasingly straightforward to link the demographic processes of birth and death with biomarkers and genetic factors, which may have concentrated some demographers' minds on the importance of such biological factors: Kreager (2009, p. 469) suggests that "the tremendous development of genetics has recalled demographers' attention to evolutionary theory as an inescapable element of modern population thought."

But perhaps, one of the most important factors for demographic interest in incorporating biological theories is that, unlike some of the other social sciences, it is not wedded to any particular theory. In fact, it has been a recurrent complaint from within the field itself that demography is a discipline without a theory (which makes it somewhat ironic perhaps, that Darwin declared Malthus had "given him a theory by which to work": see quote from his autobiography above). As early as 1952, Vance asked in the title of his *PAA* presidential address "Is theory for demographers?" The prominent demographer Livi-Bacci has described the discipline as "a technique rather than a science" (Livi-Bacci, 1984, p. iii); and a plenary at *EAPS* in 1995 by Guillaume Wunsch was titled *God has chosen to give the easy problems to the physicists Or: Why demographers need theory*. (It should be noted that this is not a universally held view among demographers: for example, in Micklin and Poston's (2005) brief survey of the theoretical basis of demography they cite Gutman (1960), who argues that demography does offer *illuminating theoretical statements* (Micklin and Poston, 2005: p. 5). Your view of whether demography is theory free or not to some extent depends on your definition of theory: Burch (2003) argues that if a theory is redefined as a model, defined in turn as an approximation of reality, rather than a set of laws from which testable hypotheses can be generated, then demography is rich in theory, because it is rich in such models).

This lack of theory has left a void, which has become particularly noticeable as demographers have become increasingly interested in individual-level rather than population-level processes, and in causal explanations for demographic phenomena: Hobcraft (2006, p. 174) called for demographers "to tackle the difficult and interesting problems of understanding behaviour, rather than undertaking elaborate description," an endeavor which really requires theory. Demography has, in fact, not been shy to borrow from other

disciplines in the past: economic thinking has, for example, been particularly influential in demographic models of the fertility transition (the shift from high to low fertility which began in Europe in the eighteenth century and has now occurred almost worldwide). To quote David Coleman (2000, p. 27) again: demography has long been "a space where other specialists come for a while to do some of their work."

Finally, important in the reunifying of demography and biology is the commitment of individual researchers to work together to solve particular problems. Two of the most prominent scientists who have worked hard to reunite the two disciplines are Jim Vaupel and Jim Carey. A social and natural scientist respectively, they have been instrumental in organizing and developing many of the workshops, courses, and the new society mentioned above. They argue that a significant factor in the progress of evolutionary demography has been the identification of particular problems that both disciplines can contribute to:

> The good intentions of top scientists are not enough to integrate two fields with fundamentally different disciplinary histories, professional cultures, and epistemological frameworks. To make progress it is imperative to lay out a clear set of important (and ultimately fundable) questions that lie at the disciplinary interface. This is particularly important for integrating disciplines with disparate historical roots, such as demography with its roots in the social and analytical sciences and biology with its roots in the natural and experimental sciences.
>
> Carey and Vaupel, 2005, p. 633

The Incorporation of Evolutionary Biology into Demography

Carey and Vaupel (2005) argue that the first few seminars described above were not particularly successful, and did not produce much in the way of outputs, because a suitable problem had not yet been identified. In more recent years, evolutionary demography has really begun to take off, after the discipline began to make significant progress in the study of aging and mortality rates at old ages. A recognition by demographers that standard demographic models failed to accurately describe the pattern of mortality at very old ages, as average longevity increased in developed nations, led to the active forging of links with the biological sciences in the hope that evolutionary models may prove useful. Models that take account of how natural selection has shaped mortality trajectories are now being used to help explain the demographic puzzle of why mortality rates should begin to plateau or decline at old ages (when standard demographic models predict *increasing* mortality rates with increasing age). A particularly notable feature of this work is its comparative nature. Evolutionary demography is not just for humans: this field has produced considerable research on how mortality trajectories vary across nonhuman species (throughout the natural world) and even on inanimate objects. This work has demonstrated remarkable variability in the shape of age-specific mortality trajectories across species, suggesting that both demography and evolutionary theories on aging need to be rethought (Vaupel et al., 1998; Jones et al., 2014). This area has also benefitted from the attention that demographer Ron Lee (2003) has given to intergenerational transfers in the aging process. Lee has used evolutionary theory to develop models of aging which incorporate intergenerational transfers as a key component influencing mortality rates, which dovetails nicely with recent work in the evolutionary sciences emphasizing the importance of such transfers in our species (Hrdy, 2009).

Work on mortality may be the most significant success story for evolutionary demography so far, but evolutionary thinking is beginning to inform other areas of demography too. In the field of reproduction, David Coleman (2000) has highlighted areas of fertility research that require biological input, for example, to explain the puzzle of why people continue to have children even when they bring only material disadvantage and when effective contraception is readily available. Such behavior is not explicable using standard demographic, typically economic, models of fertility, and can really only be explained with recourse to evolutionary arguments. Children do not appear to make one healthy, wealthy, or happy, but we do descend from ancestors who had physiological and behavioral adaptations that resulted in reproduction: any individual without such physiological abilities or behavioral tendencies toward childbearing did not become an ancestor. Empirical work by demographers developing an interest in the evolutionary demography of reproduction has tended to focus on genetic influences on reproduction. For example, early publications stemming from the collaboration of demographer Hans-Peter Kohler with psychologist Joseph Rodgers used twin study designs to ask "is fertility behaviour in our genes?" (Kohler et al., 1999; this collaboration also resulted in the publication of an edited volume on the Biodemography of Reproduction: Rodgers and Kohler, 2003). The answer was: partially, yes. More recently, Melinda Mills has been making use of technological advances in genetics and is using GWAS (genome-wide association studies: Mills et al., 2013) to explore the genetic basis to fertility behavior; again, finding evidence that genes do matter.

Evolutionary demography is having an impact on demography not just in terms of publications but also the kinds of data that are collected through the large-scale surveys demographers typically use. Studies investigating biosocial influences on demographic events are only possible if data on the potential biological and social influences on demography exist. Demographic surveys have always collected detailed socioeconomic information, but are increasingly collecting detailed biological information too. John Hobcraft, for example, is a demographer who has been influential in promoting the inclusion of biomarkers in longitudinal surveys, so that it is easier to "elaborate pathways from biology through the brain/mind to behaviors and outcomes, particularly for social, demographic, economic, and health domains" (Hobcraft, 2009, p. 252).

I will end this section with another quote from Carey and Vaupel (2005), who have argued that incorporating more biology may be essential if demography is to remain an active and important discipline:

> …every discipline including demography is faced with the perennial struggle to define and renew itself and to ensure its relevance in an

> ever changing world. Like other social sciences, demography is slowly coming to terms with important truths that the biological sciences have provided beyond any doubt: that all aspects of humans – mind, behaviour, body – are products of biological evolution. It follows that this program, in particular, and biological demography in general, should help demography maintain a robust, energetic and creative presence in modern science.
>
> Carey and Vaupel, 2005, p. 631

What Evolutionists Can Learn from Demographers

> Nothing in biology, the eminent biologist Theodosius Dobzhansky (1900–1975) asserted, makes sense except in the light of evolution. It is equally valid to say that nothing in evolution can be understood except in the light of demography
>
> Vaupel, 2003, p. 84

The section above has described work done largely by demographers becoming interested in using evolutionary theory to inform their work, but enthusiasm for the reemergence of evolutionary biology comes from both disciplines: prominent evolutionary anthropologists, such as Hillard Kaplan and Monique Borgerhoff Mulder, have also engaged explicitly with the demographic community. They have formed links with demographers, not just publishing in demographic journals and organizing sessions on evolutionary demography at population conferences, but also by setting up working groups such as the IUSSP Panel for Evolutionary Perspectives on Demography (active 2004–10, and resulting in the publication of two special journal issues).

Evolutionists bringing a more demographic perspective into their work have tended to focus largely on reproduction (unlike demographers bringing evolution into their work). Kaplan and colleagues, for example, have written influential papers on theories of fertility, both theoretical and empirical (Kaplan, 1996; Kaplan and Lancaster, 2003). These papers draw on the demographic literature but incorporate elements of life history theory (the evolutionary framework relevant for studying demography), such as parental investment, and also give a historical perspective on reproductive behavior over time. Kaplan has also helped move forward debates in demography, by directly setting up tests of alternative hypotheses, where social and evolutionary explanations of fertility behavior are in conflict (though frequently evolutionary and social science explanations are not in conflict with one another, because they explain the same phenomena at different levels: Sear, 2015). For example, he empirically contrasted two models of intergenerational resource flows, which have been used in theories of the demographic transition. The influential demographer Jack Caldwell's "wealth flows" hypothesis for the demographic transition argues that in predemographic transition societies, net wealth flow is up generations, from children to parents. Evolutionary theory, on the other hand, predicts that net wealth flow will always be downward, from parents to children: wealth is always used in the service of reproduction, never the reverse. Kaplan (1994) tested these alternate models by measuring the economic costs and benefits of children in hunter-gatherer societies. His findings suggested that, contra Caldwell's wealth flows hypothesis, children were always a net economic cost to their parents, even in traditional subsistence societies. This does not mean that changes in the costs and benefits of children were not factors in the demographic transition, or that children never provide benefits to their parents, just that this one assumption of the wealth flows hypothesis was not supported.

The benefits of such cross-fertilization for the evolutionary community include borrowing from the methodological sophistication of demography, not just in formal but also statistical analysis of demographic data and the use of large-scale, longitudinal datasets. Kim Hill and Magdalena Hurtado produced one of the earliest monographs in evolutionary ecology, which made heavy use of statistical techniques and advances in demography, such as the use of event history models for demographic events. Their book *Ache Life History: The Ecology and Demography of a Foraging People* (Hill and Hurtado, 1996) was an impressive tour de force testing a wide range of hypotheses derived from life history theory using their longitudinal data set on the Ache, South American hunter-gatherers, and was very influential in shaping the developmental of the field of human evolutionary ecology (the study of physiology and behavior in ecological context, within the framework of evolutionary theory). Other evolutionary ecologists have followed in their footsteps, testing hypotheses on demographic data deriving from evolutionary theory but making use of the methods developed to analyze human demographic data. Increasingly, evolutionary ecologists are also making use of large-scale data sets collected by demographers, seeing an opportunity to test their hypotheses on existing large, rich data sets, rather than relying on small-scale data collection in 'traditional' populations (Nettle et al., 2013).

Remaining Differences of Opinion

The positive overview I have given so far should not be taken to mean that the discipline of evolutionary demography is entirely uncontroversial, nor that all demographers are comfortable with the idea that biology matters for human demography. In some quarters at least there still may be the view that biological and social explanations are alternates so that when trying to explain any human behavior "biology and the social are locked in an explanatory zero-sum game in which any ground ceded to the former diminishes the value of the latter" (Carey and Vaupel, 2005, p. 642–643). On the other side of the fence, some evolutionists have yet to fully engage with demographers to improve their understanding and analysis of the demographic phenomena they are interested in. There are also still conceptual differences between the two disciplines in that demography is a 'bottom-up' science, which starts with an empirical observation and subsequently attempts to explain that phenomenon (such as why does fertility decline?); whereas evolutionary biology is a 'top-down' science, which sees data as a means to an end to test hypotheses which derive from an overarching theoretical framework (Kaplan and Gurven, 2008). This primary interest in data versus theory means that the two disciplines will always have distinct and separate goals, but there is still sufficient overlap between the disciplines for the increasing interaction between the two to be scientifically fruitful.

Conclusion

Of all of the social sciences and humanities, demography seems perhaps to be one of those disciplines where a Darwinian renaissance is genuinely underway. Kreager, for example, wrote in 2009 (p. 471) that "evolutionary biology, *of course*, re-emerged in the 1990s as a potential source of evidence and theoretical insight into central demographic problems" (emphasis added). This is partly because renaissance is the right term to apply in the case of demography, given the close association of the two disciplines during their early development. But also because there is evidence of an emerging discipline of evolutionary demography, driven by both evolutionary scientists and demographers recognizing the need to draw on each other's expertise. Indeed, this discipline has not just emerged but is sufficiently well established to be "com [ing] of age" and "entering its adolescence" in the words of one author who contributed to a special issue on biodemography in the demography journal *Demographic Research* (Wachter, 2008, p. 1501). I will leave the last word to the demographer and biologist who have perhaps done the most to establish this discipline.

> Although still a modest subfield within demography, biodemography may be one of the fastest growing areas of demography and one of the most innovative and stimulating

Evolutionary Demography: A Synthesis of Two Population Sciences

Daniel A Levitis, Max-Planck Odense Center on the Biodemography of Aging, University of Southern Denmark, Odense, Denmark

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Demography is the quantitative study of population processes, while evolution is a population process that influences all aspects of biological organisms, including their demography. Demographic traits common to all human populations are the products of biological evolution or the interaction of biological and cultural evolution. Demographic variation within and among human populations is influenced by our biology, and therefore by natural selection and our evolutionary background. Demographic methods are necessary for studying populations of other species, and for quantifying evolutionary fitness. Comparisons among species allow for a greater understanding of how and why demographic patterns evolve.

Twin Population Processes

Shared Concepts and Focus

The field of demography arose as, and largely remains, a social science. It generally restricts itself to human populations, and the causative hypotheses it tests are based in sociology, economics, history, psychology, cultural anthropology, and other social sciences. Despite this cultural tendency, the underlying phenomena demography describes are strongly influenced by biology, and therefore, by biological evolution. Indeed, the central concepts of demography – including mortality, fertility, migration, populations, sociality, behavior, heterogeneity, heritability, stochasticity, resource flows, and environmental influences – are all also central to evolutionary biology. Evolutionary demography expands the scope of demographic research by considering nonhumans, and employing methods, concepts, and hypotheses from evolutionary biology. As such, it allows us to ask questions about the origins of demographic patterns that are otherwise unanswerable.

Separate literature regarding, for example, economic consequences of marriage markets in humans and fitness effects of assortative mating in all other species arise with distinct methods for quantifying extremely similar phenomena. Linguistic differences between fields (e.g., what demographers call 'fertility' and 'migration' biologists call 'fecundity' and 'dispersal') are symptomatic of a historical dearth of communication between social and natural scientists. (**Box 1** provides definitions of some relevant biological terms.) The study of evolutionary demography aims to cross these artificial barriers to mutual illumination by combining the concepts and tools of demography and evolution, thereby broadening the scope of both fields.

This article deals specifically with the intersection of evolution and demography, and (because the field of biology is much broader than the study of evolution) excludes much of the broader category of biodemography. For example, biomarkers of aging are often measured or the demography of nonhuman populations quantified without reference to concepts or tools derived from evolutionary biology. Other sections in this encyclopedia focus on topics in biodemography.

Evolution as Demography

While demography is defined as the quantitative study of population processes (Preston et al., 2000), evolution is a population process and, therefore, inherently demographic (Kohler and Rodgers, 2003). Evolution through natural selection can occur only when heritable traits influence the demography (survival or reproduction) of their bearers. The calculation of fitness requires consideration of not only the demographic effects of a trait, but also demographic characteristics of the population, including age structure, stochasticity, and population growth rate (Metcalf and Pavard, 2007). Evolutionary processes beyond selection, such as genetic drift and mutation, are strongly influenced by the size and characteristics of the population.

How Demography Evolves

In outline, the evolution of demographic traits is little different than that of morphological, physiological, or behavioral traits. Alleles that influence any of these phenotypic traits change in frequency over time through selection, recombination, mutation, and drift. The difference, in this context, between demography and these other aspects of the phenotype is that other traits influence fitness, and therefore selective outcomes, only via demography. More specifically, any trait that does not influence survival or reproduction has no fitness consequences, while one that increases survival or reproduction will tend to increase fitness. This implies both that demography is the aspect of phenotype most tightly tied to fitness, and that any response to selection influences the demography of the population.

The classic example in evolutionary demography is an allele that decreases susceptibility to a deadly disease at a particular age and therefore allows its bearers to continue reproducing, increasing the frequency of that allele and therefore the longevity of the population (see Kirkwood, 2005; Wachter et al., 1997 and references therein for review of evolutionary theories of aging). However, if selection strengthens the wood of a tree, or the linguistic ability of a primate, the demography of the population has also perforce been influenced. The resulting change may be quickly countered by density effects (such as food or space limitation) or the population may end up more longevous or fertile. Any instance of selective

Box 1 Definitions of key biological terms for evolutionary demography

Allele: One form of a gene. For example, two copies of the same chromosome may have slightly different forms of a gene that when functioning properly, helps to protect against breast cancer. Different alleles may offer different degrees of protection, with the null allele (a mutated form that fails to produce a functional product) offering no protection.

Dispersal: Movement of individuals from one site to another, generally noncyclical. This is what demographers would generally call migration.

Evolution: change in the genetic composition of lineages over time, and changes in the phenotype that result from this genetic change. Evolution results from selection, genetic drift, migration, mutation, and genetic recombination.

Fertility: The physiological capacity to reproduce, which demographers call fecundity.

Fecundity: How many offspring the individual actually produces, which demographers call fertility.

Fitness: The mean ability of individuals of a particular phenotype or genotype to get copies of their genetic material into future generations. Fitness is calculated in a variety of different ways (Metcalf and Pavard, 2007), but all depend on reproduction and survival. Fitness depends on both the characteristics of individuals and the particular environment in which it is measured.

Genetic drift: Change in allele frequencies that result not from selection or mutation, but rather stochastic changes in what proportion of the population carries each allele. Demographic stochasticity, whose effects decrease with population size, is a key driver of genetic drift.

Genotype: The set of alleles possessed by an individual, sometimes considered across all genes (the genome) but often in reference to only those genes that have bearing on the trait of interest.

Individual: The unit considered to be a separate entity, often by tacit analogy to an individual human. In some organisms, it is necessary to consider carefully how the individual is to be defined before demography can be examined.

Migration: Long-distance cyclical movements, often seasonal, back and forth between habitats.

Mutation: A change in the sequence of nucleotide (DNA or RNA bases) that constitutes the genome of an organism, or a new allele that results from such a change. While some mutations are beneficial and many are deleterious, most do not alter demography and, therefore, have no effect on fitness.

Phenotype: The organism's observable traits. Phenotype results from the interaction of the genotype with the environment.

Phylogeny: The evolutionary relationships among species or populations reflecting their common ancestry, often represented as a branching tree.

Selection: The differential survival or reproduction of individuals based on their phenotype. If these phenotypic differences are heritable, an evolutionary response to selection (change in allele frequencies) can occur.

Senescence: Where demographers usually define senescence in terms of declines in survival probabilities or reproductive rates with age, biologists more often refer to declines in function, such as slower healing or locomotor speed. Evolutionary demographers tend toward the demographic definitions unless otherwise specified.

evolution can, therefore, be thought of as favoring a morphological/physiological/and so on trait that is directly influenced by the genes, or as favoring the demographic effect of that trait. Selection for larger testes (which are useful in species that engage in sperm competition) can also be considered to be selection for higher investment in fertility.

So while evolution is a demographic process, the demography of any biological population is shaped by its evolutionary history. That humans begin reproducing after more than a decade, while small monkeys do so after one or a few years, for example, is a result of evolution. Indeed, any demographic trait that distinguishes humans from other species is at least in part the result of the evolved biological differences between humans and others. That human demography has changed so rapidly in the last centuries is surely an example of cultural evolution (Burger et al., 2012), but the fact that we have the linguistic, cognitive, and social abilities to change our culture so quickly (while chimpanzees, for example, do not) is the result of the biological evolution that has separated humans from related species. Biological evolution should not, therefore, be seen as an alternative to cultural evolution. Rather, our biological history constrains and allows for our cultural behaviors, and those behaviors determine our environment, and thereby, how our biological traits continue to evolve. Human culture and biology jointly and collaboratively drive the evolution of human demography.

In addition to demography and evolutionary biology, evolutionary demography intersects with a wide range of other fields, including anthropology, gerontology, epidemiology, evolutionary medicine, behavioral ecology, and reliability engineering.

Selective Explanations for Human-Demographic Traits

Optimality and Constraints

Evolutionary demography expands the scope of demography by considering evolutionary explanations for demographic traits. These are most often framed in terms of natural selection,

with the fundamental idea that selection pushes populations to achieve the optimal set of traits (Chu et al., 2008), with optimality defined as the maximization of fitness. Infinite reproduction starting immediately after birth coupled with zero mortality is the impossible limit toward which fitness maximization points. That this circumstance is quite impossible is because all organisms and populations operate within a variety of constraints imposed by their environment and internal biology. Increasing all fitness components simultaneously would certainly be favorable, but not feasible. Understanding the evolution of demography, therefore, frequently requires us to ask what has constrained that evolution.

The constraint that evolutionary demographers most often consider is that of resource limitation. An organism is modeled as partitioning its income at each age (in the currency of calories or time, for example) among a variety of investments (increasing current survival, current reproduction, growth, etc.). A unit of resource can buy so much growth, survival probability, and so on and income is limited by factors that may include size or investment in foraging (Chu et al., 2008). A variety of techniques are then available for finding the investment strategy that maximizes fitness. These techniques are often successful in predicting key features of life histories, such as the prereproductive growth phase, the onset of senescence at age of first reproduction, and sex ratios near parity.

This reasoning provides key hypotheses on the evolution of human demography. Onset of reproduction then occurs at that age where the tradeoff between fertility and continued growth shifts to favoring reproduction. Infant and child mortality, under this optimality-with-resource-constraints framework, result from strong selection for early investment in growth, at the cost of investment in current survival (Chu et al., 2008). Or they can be understood, by applying resource constraints at the level of the food-sharing group, rather than the individual, as resulting from the negative but increasing economic value (in terms of transferable calories) of dependent young (Lee, 2003). Women's postfertile survival can similarly be considered as resulting from their optimal allocation including the resources necessary to keep them alive to continue investing in the survival and reproduction of their children and grandchildren (reviewed in Pavard et al., 2008). Senescence, in this resource-constraint framework, is the result of investment in reproduction and current survival having a higher payoff than investment in traits that maintain future survival and reproduction.

However, resource limitation is far from the only constraint acting on the outcomes of selection as it shapes demography. Staying with the example of senescence, the genetic basis of demography must be considered. A single allele may affect multiple traits (pleiotropy), for example, increasing reproduction at one age while decreasing survival at all ages, or at a particular age. Selection can increase or decrease the frequency of this allele in the population but it cannot generally decouple the positive and negative effects. Where the total effect on fitness is positive, the allele will tend to become more common until it goes to fixation. For example, traits expressed early in life tend to have a greater effect on fitness than those occurring later in adult life, even if the magnitude of the effect is smaller. This is true both because a smaller proportion of individuals will be alive to express a trait later in life and because mortality later in life occurs after a larger proportion of the individual's reproduction has already occurred. Antagonistic pleiotropies (where some fitness effects are positive and other negative) tend to increase early reproduction and survival at the cost of later success, resulting in senescence. This is still fitness optimization, but with genetic rather than resource constraint.

A similar result can be obtained without assuming that optima are attainable, on the basis of mutation-selection balance. While selection tends to increase the frequency of alleles that maximize fitness, random mutations generally decrease fitness. The allele frequencies that result when selection and mutation act simultaneously will depend in part on how strongly selection acts to remove mutations. Among other things, this depends on the ages at which alleles have their fitness effects. Again, mutations that act later in life will tend to have less of an effect of fitness, and therefore be removed less efficiently, allowing accumulation of mutations that increase mortality and decrease fertility later in life. The constraint here derives from the fact that selection itself is only so powerful in determining the rates of available traits.

A further set of constraints arises from the fact that many potentially desirable phenotypes simply do not occur. The ability to reproduce asexually when no mate is available does not occur in any mammal and therefore probably would not occur in humans even if it was strongly selectively advantageous. While no demographer would assume facultative clonality in humans, our models do sometimes include traits that we have good reason to believe are impossible. For example, models in evolutionary demography frequently assume perfect age specificity of gene effects, such that selection can cause fertility to start increasing at an exact age, or mortality to approach infinity at the exact age when reproduction ends (see Levitis et al., 2013 and references therein). Perfect age specificity is a convenient simplifying assumption, but a false one. While average gene expression does change as a function of age, a remarkably small proportion of variance in expression is age specific. Furthermore, the demographic results of age-specific gene expression (whether genetic diseases or events in the normal healthy human life-history) often occur not when a gene is turned on or off, but after some product or effect of expression, influenced by environment and by feedback in regulator networks, has accumulated or attenuated, gradually increasing the probability of that event. Put more simply, even if gene expression changed rapidly as a function of age, phenotypic results may come more gradually. At the demographic level, this results in trajectories of gradually changing rates, rather than discontinuous changes (Cohen et al., 2012). An allele that would cause a particular abrupt change in an age profile of mortality or fertility might be optimal, but it also probably does not exist.

A related reason, the optimal trait may not exist can be found in Charles Darwin's (1859) favored description of evolution, 'descent with modification.' Evolution functions by gradually modifying traits of a lineage, and traits that are too dissimilar from parents have near zero probabilities of arising in descendants. If some small portion of the population already has the preferred trait, or something close to it, change can occur rapidly, but where heritable variation does not exist, or does not include traits preferable to the current norm, selection can do little. Imagine, for example, that in a given environment it would be highly selectively advantageous for women to cease reproducing at age 45 but then resume fertility at age 65, after

two decades of child rearing and physiological recovery. Natural variation in women's reproductive physiology does not include this or useful intermediate traits (there is no unmenopause), so the hypothetical trait cannot be selected for.

Traits Shared by All Human Populations

Causal hypotheses in demography most often focus on explaining variation within and among populations. Evolutionary demography, by contrast, has often focused on explaining specific portions of the patterns shared by all human populations. Looking at human age-specific mortality curves (**Figure 1**), for example, demographers most often ask why the curves differ from each other in some respect, or what characteristics of individuals determine who dies at each point along the curve. Why is infant mortality higher in some than others? Why does the bump in the teenage years get earlier in richer societies? Why do some adults die at the age of 40 years and others 90 years? Evolutionary demography often focuses on the similarity among these curves, explaining them with hypotheses based in selection and constraints on its actions. High but declining early mortality (i.e., ontogenescence) is explained in terms of optimality, as described above, but also in terms of mechanistic constraints and heterogeneous frailties (Levitis, 2011). The period of increased mortality observed early in adulthood and primarily in males (the adolescent mortality hump) is proposed to be the result of selection for risk-taking behaviors that increase reproductive opportunity (Kruger and Nesse, 2006). In contrast, no widely accepted hypothesis has been proposed to explain why senescent mortality is close to exponential in its increase over a wide range of adult ages.

Human fertility traits are also evolved, and aspects such as age at reproductive onset, interbirth intervals, twinning rates, offspring size, and age at reproductive cessation are addressed by evolutionary hypotheses (Wachter and Bulatao, 2003). One key aspect of human reproduction, the need for a large-headed baby to pass through a biped's narrow pelvis during birthing is both a legacy of evolution (all vertebrates that have pelvic bones pass their offspring through them) and may have had serious consequences for the evolution of human demography. This 'Obstetric Dilemma' may, by limiting infant head size, have increased the length and severity of the juvenile dependence, and women's evolved postfertile life stage likely evolved as a result of human socioecological responses to this dependence (Robson et al., 2006). That the ratio of offspring head size to maternal pelvic opening in humans is similar to that of related species has been taken as evidence against this hypothesis (Dunsworth et al., 2012), but can also be seen as evidence for a constraint that occurs more broadly than just humans. In other words, if human infant head size was already at the limit determined by primate pelvic morphology, but selection pushed for adults with bigger brains, this may have required an increase in the proportion of neurological development that occurs after birth.

Figure 1 Human patterns of mortality over age are remarkably similar in form across populations. Data shown (from highest mortality to lowest) are Sweden in the 1750s, Taiwan in the 1920s, Sri Lanka in the 1980s, Belarus in the 1990s, and Japan in the 2000s. Cohort and male mortality curves have the same basic shape as these female period data (Human Life-Table Database and Human Mortality Database, 2013. Rostock, Germany and Berkeley, CA: UC Berkeley and Max Planck Institute for Demographic Research. www.mortality.org).

Few aspects of evolutionary demography receive as much attention from the public as the quest to understand women's postreproductive life span. While most other species seem, at least in their natural environments, to experience declines in fertility and survivorship roughly simultaneously, women across environments lose fecundity well before they die (or keep living after their fertility has declined to zero). A remarkable range of hypotheses (reviewed in Robson et al., 2006; Pavard et al., 2008; Levitis et al., 2013; Wachter et al., 1997) have been proposed to explain why. These focus on the roles of mothers and grandmothers in aiding younger kin, on the continued reproduction of older men and the genetic correlations between male and female and on avoidance of intergenerational competition, among many other selective arguments.

These are but a few examples: any demographic pattern that occurs across human populations should be interrogated as to its evolutionary basis. Doing so expands the scope of demography by allowing explanation of traits that can otherwise be noticed and measured but not explained.

Variation among Humans

Those demographic patterns that vary within and among human populations are less often subject to evolutionary hypothesizing for two good reasons. The first of these is that there exists a long troubling history of using evolutionary language and biased evolutionary arguments to rationalize discrimination, and many social scientists are, therefore, wary of biological explanations for behavioral or demographic differences among people. The second is that humans are tremendously culturally diverse but biologically fairly uniform, and the biggest demographic differences among us are, therefore, likely to be cultural in origin. Despite both of these good arguments, some demographically relevant human traits are appropriately explained in evolutionary terms. These differences can be placed into two rough categories: evolved differences and evolved plasticity.

When populations and individuals differ in their genetic predispositions to suffering from certain potentially deadly

diseases (e.g., certain cancers, sickle cell anemia), we can ask about potential fitness benefits of particular alleles, about the role of mutation, genetic drift, breeding patterns, and so on. In other words, we can understand these demographically significant differences in evolutionary terms. This same reasoning applies to many demography-influencing traits that are, or may be, heritable (Kohler and Rodgers, 2003).

Contrast this with evolved plasticity, which does not require heritable differences, but instead that the same set of genetic traits can be expressed in different (often selectively advantageous) ways in different environments. For example, the thrifty phenotype hypothesis (Hales and Barker, 2001) argues that individuals who undergo early development in a nutrient poor environment can respond to this by altering their development such that they are better able to deal with low-nutrient environments late in life.

Evolutionary reasoning can be helpful in understanding demographically important behaviors with more potential for controversy. Patterns of infanticide, for example, can be explained in terms of caretakers' degree and confidence of relatedness to those they are related to and the potential for redirection of parental resources (Dixson, 2013). Demographic transitions can be modeled as resulting from evolved economic behaviors and a changing environment (Borgerhoff Mulder, 1998). While there may be limits on the aspects of human demography that should be described in evolutionary terms, there are no obvious limits on the aspects that can be so described.

Demography beyond Humans

The Application of Demography to Nonhumans

Humans have unique patterns of mortality, fertility, and migration but are not unique in having mortality, fertility, and migration, and so it is not surprising that demographic methods (e.g., survival analysis) have long been adopted and adapted by biologists and ecologists to quantify the population processes of species beyond demography's traditional boundary. The motivation for these efforts varies from the applied (How many fish of what size can we catch sustainably? How quickly can this introduced pest population grow? Does this medicine extend life span in mice?) to the basic (Is sexual reproduction associated with higher offspring viability? Does copious food promote earlier natal dispersal?) and theoretical (If an organism could exponentially increase its reproductive output indefinitely, would it still be expected to evolve aging?). Indeed, demographic methods influenced by those originally developed to study humans are included in the basic quantitative toolboxes of wildlife biology, conservation biology, forestry management, population ecology, behavioral ecology, zoo management, and a wide range of other disciplines focused on nonhumans.

Challenges in Nonhuman Demography

It is not always straightforward to apply the methods of anthropocentric demography to other species. Simplifying assumptions that are safe for humans are often violated by other species. Particular nonhumans may reproduce by fission, switch sexes, experience extended periods of dormancy, have several very different life stages that reproduce in multiple ways, return to earlier stages of development, repeatedly lose and regenerate the majority of their tissues, return from apparent death, merge with or incorporate the genetic materials of others, and employ a dizzying array of tactics that confound any traditional demographic analysis. An attempt to study the longevity of sea sponges in the wild, for example, may be foiled by the difficulty of simply determining what an individual is, given ceaseless splitting, rejoining, fragmentation, disappearance, and reappearance (Tanaka, 2002). While age is a key variable in human demography, it is an ill-defined term of little use when individuals cannot be spatially and temporally demarcated. So while human-demographic methods may apply almost without modification to some species (many birds and mammals, for example) evolutionary demography employs and develops an array of modified or alternative methods for studying similar phenomena.

Adding to the need for alternative or modified methods are the particular data problems experienced when studying nonhumans. Nonhumans can generally not be expected to answer survey questions or report births and deaths. Individuals of some species are extremely difficult to recognize, mark, track, or even define. The underlying biology of a species may be poorly known. On the other hand, some species have distinct advantages for the researcher. Many trees provide a reliable means to determine an individuals' age (counting rings) without tracking over time, are unable to leave the study area and never decline to participate.

Methods for Nonhuman Populations

Where age is a key variable, human specific age-based methods can often be directly applied to nonhumans. Life tables, age-specific fertility, survival analyses with age-specific baseline functions, and many other common demographic tools are successfully applied to some animals, plants, fungi, bacteria, and so on. Where other key variables (stage, size-class, etc.) dominate or interact with age, some tools from the demographers' toolbox, including many regression methods, can still usefully be applied. But in these circumstances many tools less often employed by demographers, including a variety of purpose-built matrix models, are favored. These models often incorporate transition matrices mapping stochastic paths through several possible life stages. Where in human demography these stages could be never married/married/divorced, in crab demography they could be egg/planktonic larva/pre-breeder/breeding adult/nonbreeding adult. Some stage-based models are expanded to also include age. Integral Projection Models combine matrices with regressions to model the effects of continuously varying factors (e.g., rainfall) on the various matrix elements. Mark-recapture data, in which individually identifiable animals (zebras with identifying stripes or sea stars with tattoos) are repeatedly recorded and released are commonly used to study demography, and a variety of tools have been built for this purpose.

Studying nonhumans allows for the use of experimental methods that would otherwise be impractical, unethical, and illegal. These experiments can be used to document the demography of a particular species and how it depends upon

environment, to test a hypothesis about how demography evolves by applying a selective pressure over several generations, or to alter the genetic makeup of a population and examine how demography is affected.

Evolutionary Comparative Demography

Comparisons across Species

Evolutionary demographers often examine demographic variation among species. To understand how a demographic trait of humans (or any other species) has evolved, one needs to know what it evolved from (the evolutionary history of the trait), how widely it occurs, what traits it cooccurs with, what alternatives are biologically possible, and so on. Knowing these things requires comparisons across species.

While no other species' demography has been as thoroughly studied as that of humans, some aspects of demography have been documented in thousands of plants and animal species, allowing for broad comparison. The goal is generally to answer an evolutionary question. For example, Do higher metabolic rates lead to shorter life spans? Evolutionary demography overlaps extensively with life-history evolution, and many of the hypotheses tested derive from that literature.

Comparative Measures, Methods, and Data

Serious challenges exist not only in the types and quality of data that are available, but also in compiling the existing data from a wide variety of sources and building sensible comparisons between organisms that live in different ways and have been studied by people whose methods are often not designed for comparisons to other species. For example, maximum observed longevity, while far from an ideal measure of how long a species lives, has often been employed for comparative purposes because this is a relatively easy datum to record and compile and is a defined (if not known) quantity for every type of organism for which individuals can be identified. Because different species' demography occurs on different timescales, useful comparative measures are often dimensionless (Charnov, 1991) or explicitly corrected for the pace at which each species proceeds through life (Baudisch et al., 2013).

Once measures are chosen, a variety of methods from evolutionary biology are useful for comparative demographic studies. Allometric methods aid in the consideration of traits that scale with the size of the organism (e.g., longevity with body or brain mass) in a nonlinear fashion. Allometric relationships take the form $Y = a^{*}X^{Z}$. Y is the trait of interest, X is size, and a and z are fit coefficients. z, the scaling factor, describes how quickly Y increases with increase in X. Most life-history measures increase with size, but inherent physical constraints on the scaling of circulatory systems limit metabolic speeds such that larger organisms tend to use less energy per unit mass (West et al., 1997). As a result, z is often roughly 1/4, across a remarkable range of physiological and life-history measures and across many taxa. For example, the life span or age at first breeding of an organism of twice the size will tend to be about 1.2 times as long.

Phylogenetic methods, which explicitly take into account the evolutionary tree connecting the lineages being considered, are frequently required for comparative evolutionary demography (Stearns, 1983). Because closely related species are likely to share characteristics through common inheritance, it is not appropriate to treat them as independent samples in a cross-species analysis. The less close the relationship, the more independence we generally expect to see. A wide range of methods are available to estimate and correct for the degree to which this so-called 'phylogenetic inertia' is influencing a trait or the relationship between traits. Phylogenetic methods are used for a wide range of purposes, including estimating when a particular trait evolved, and thereby what other traits or events influenced its evolution.

Just as comparisons among humans are greatly aided by demographic databases, comparisons among species will become much easier as biodemographic databases come on line. Some, such as AnAge (offering primarily maximum observed longevity (De Magalhaes and Costa, 2009)) are already available. Others offering far greater demographic detail in the form of matrix models or life tables are under construction but not yet freely available.

Widely Occurring Traits

Comparative methods and comparative databases are particularly useful when a trait varies. If every species in a database has the same trait value, comparisons among them are not informative. A study of the demographic effects of sexual reproduction, for example, would not use a database on the demography of birds and mammals, all of which reproduce sexually. This is obvious, but has a potentially less obvious correlate: a widely occurring trait should be explained with a widely applicable hypothesis. A parsimonious explanation should explain sexual reproduction in all birds, and not just in moorhens. The same principle should be, but is often not, applied to humans. In order to ask why adult mortality increases exponentially with age, we should ask if this is true only in humans, or across all primates, mammals, vertebrates, or animals. To understand why women have a long post-reproductive life span, it is useful to ask if it is evolutionarily derived trait, or only a longer version of a trait that occurs across species (Levitis et al., 2013). Many, perhaps most, demographic traits that occur across all human populations have close parallels in related species in a way that implies homology (i.e., humans and our relatives coinherited, rather than independently deriving, these trait). One can always ask why humans have not evolved to modify or discard the inherited trait, but this is often fruitless, especially if the origin of the trait is not well understood. Where a trait is found beyond humans, a human-specific explanation is of limited value in explaining the origin of the trait (e.g., a pre-reproductive period), but can still be useful in explaining the details of why humans have a modification of the same trait (e.g., a longer prereproductive period).

So while evolutionary demography helps to expand the boundaries of demography (in terms of hypotheses, patterns, taxa considered, and methods used) applying evolutionary reasoning to demographic problems also usefully constrains the tendency to consider humans in a vacuum. It does so by placing us in the context of other species with which we share demographic traits, biological mechanisms, and evolutionary

history. That such interspecific comparisons are outside the tradition of demography only increases their capacity to expand our knowledge of population processes.

Evolutionary Developmental Psychology

Karin Machluf and David F Bjorklund, Florida Atlantic University, Boca Raton, FL, USA

Abstract

Evolutionary developmental psychology posits that natural selection operates across the lifespan and focuses on how psychological mechanisms develop. The basic tenets of evolutionary developmental psychology are outlined, along with detailed discussion of ontogenetic, deferred, and conditional adaptations. These are then applied to mental health, where the mental health model is pitted against the evolutionary developmental perspective of mental health. Lastly, adolescent risk-taking behaviors are examined from an evolutionary-informed perspective using life history theory to explore the influence of environmental harshness and unpredictability in early childhood.

Development and Evolution

The intimate connection between development and evolution has long been acknowledged. Darwin, in his controversial and revolutionary book *The Origin of Species* (1859), meticulously described the processes of embryology, as it was understood then, and used it as part of his indisputable evidence for evolution (*see* Darwinism). In a letter to a his colleague, Asa Gray, Darwin wrote, "Embryology is to me by far the strongest single class of facts in favor of change of forms, and not one, I think, of my reviewers has alluded to this" (1860). He concluded that if slight changes are introduced across different points of time, for different parts of the body, it would produce different forms that are adapted to those particular circumstances.

Darwin's assessment of the importance of development was correct but simultaneously premature. Darwin knew nothing of genetics, and the rediscovery of Mendel's work in the early 1900s and August Weismann's doctrine of the separation of the germ and somatic lines (what happens to the body cells of an organism during its lifetime cannot influence the content of its sex cells), resulted in the temporary parting of ways of development and evolution. The field became 'gene-centric,' integrating Mendelian genetics with Darwin's ideas of natural selection, leading to *neo-Darwinism*, or the *Modern Synthesis* (Huxley, 1942). This reflected the official acceptance by the scientific community that large-scale changes in form could be explained by small genetic changes acted upon by the process of natural selection, over long stretches of time, to produce variations within species. From this perspective, development did not matter, or, as more elegantly expressed by Richard Dawkins (1976/2006: p. 62), "The details of embryological developmental processes, interesting as they may be, are irrelevant to evolutionary considerations." Development, although of vital importance to the individual, was essentially inconsequential to natural selection and thus evolution.

In the past few decades, however, the focus on development has reemerged in evolutionary thinking, with, for example, Stephen Jay Gould's *Ontogeny and Phylogeny* (1977), reinvigorating the idea that modifications during development may influence evolution, Eva Jablonka and Marion Lamb's *Epigenetic Inheritance and Evolution* (1995), proposing the role of epigenetics in evolution (see also Jablonka and Lamb's 2005 book, *Evolution in Four Dimensions*), and Mary Jane West-Eberhard's *Developmental Plasticity and Evolution* (2003), extending epigenetics to developmental plasticity (*see* Epigenetic Inheritance). Over the last two decades, evolutionary thinking has entered the mainstream of psychology, and most evolutionary psychologists have modified the now-famous quote by Theodosius Dobzhansky (1973: p. 749) stating that "Nothing in biology makes sense except in the light of evolution" to "Nothing in psychology makes sense except in the light of evolution."

The central concept of Darwin's theory of evolution is *natural selection*, which assumes that more members of a species are born in a generation than will survive, resulting in competition for a set of limited resources (*see* Microevolution). Individuals vary, and those that have features associated with greater survival will pass those features to their offspring. In other words, heritable variations in characteristics of an individual interact with the local environment, and, over long periods of time, change in frequency, resulting, eventually, in specieswide traits in the population.

Evolutionary psychologists realized that natural selection could be used to explain species differences in psychological as well as physical features, and thus could be used to explain and predict many aspects of human behavior (e.g., Buss, 1995; Daly and Wilson, 1988; Tooby and Cosmides, 1992; *see* Evolution of Cognition: An Adaptationist Perspective). The principal focus of mainstream evolutionary psychology was understandably on adults, who do the reproducing, the ultimate measure of Darwinian success. Much like biologists of an earlier era, many evolutionary psychologists saw development as an epiphenomenon, interesting and important for the individual, but little more than 'noise' when it came to important psychological characteristics that typify *Homo sapiens*. Yet, individuals must survive the often-hazardous periods of infancy and childhood before reaching adulthood, where the reproducing (and subsequent rearing of children) takes place. In fact, although the likelihood of a newborn dying before reaching adolescence today is about 1% in Western cultures, it is closer to 50% in traditional societies and was likely as higher or higher for our ancestors (Volk and Atkinson, 2008). This makes childhood the crucible of evolution, such that any adaptations that increase the chance

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81018-1

of surviving to adulthood during these earlier stages of life would certainly be favored by natural selection.

Evolutionary Developmental Psychology

Natural selection operates at all stages of the lifespan; however, it operated at some stages more than others, especially early in development. From this realization was born the field of *evolutionary developmental psychology* (e.g., Bjorklund et al., 2007; Bjorklund and Pellegrini, 2000, 2002; Bjorklund and Hernández Blasi, 2005; Burgess and MacDonald, 2005; Ellis and Bjorklund, 2005; Geary and Bjorklund, 2000). Evolutionary developmental psychology is defined as the application of the basic principles of evolution to explain contemporary human development: "It involves the study of the genetic and environmental mechanisms that underlie the universal development of social and cognitive competencies and the evolved epigenetic (gene–environment interactions) processes that adapt these competencies to local conditions; it assumes that not only are behaviors and cognitions that characterize adults the product of selection pressures operating over the course of evolution, but so also are characteristics of children's behaviors and minds" (Bjorklund and Pellegrini, 2002: p. 4). It posits that natural selection operates throughout ontogeny (i.e., the lifetime of the individual), not simply during an organism's reproductive years.

In this article, we first outline briefly some of the principles and assumptions of evolutionary developmental psychology (see Bjorklund and Pellegrini, 2000, 2002). We then look at how an evolutionary developmental psychological approach can be applied to the study of developmental psychopathology. We specifically contrast the canonical mental health model, which generally emphasizes *costs* and largely ignores any *benefits* of children's responses to risky environments, with an explicitly evolutionary developmental perspective. Finally, we discuss how this evolutionary developmental perspective can help better understand risk-taking and antisocial behaviors, especially in adolescence.

Some Basic Principles of Evolutionary Developmental Psychology

A central concern of evolutionary developmental psychology is how psychological mechanisms develop. In fact, this, some believed, is what mainstream evolutionary psychological theory was lacking. How do inherited, presumably genetically coded behaviors and cognitions get expressed in the phenotypes of adults? The obvious answer seems to be 'through development,' and in this section we examine some of the basic principles of evolutionary developmental psychology.

All Evolved Characteristics Develop via Continuous and Bidirectional Gene–Environment Interactions That Emerge Dynamically over Time

One problem that many people have with an evolutionary approach to human behavior is that there is the taint of *genetic determinism*, the belief that if a behavior or type of cognition evolved and is influenced by genes (which are, after all, the basic units of inheritance), then there is little one can do to change 'human nature'; that is, genes directly cause, or determine, behavior (e.g., Spencer et al., 2009; Lickliter and Honeycutt, 2003). Such an approach is generally anathema to developmental psychologists, accounting, in part, for the reluctance of some developmentalists to adopt an evolutionary perspective. However, evolutionary developmental psychologists have adopted a *developmental systems approach* (Gottlieb, 2002, 2007), which stipulates that genes and environment interact at all levels of organization, from the biochemistry of the cells through culture. From this perspective it is inappropriate to ask 'how much' of any feature (physical or psychological) is the result of 'nature' vs 'nurture,' but rather about ascertaining how do the biological and environmental factors interact to produce those features.

At the core of the developmental systems approach is the concept of *epigenesis*, which Gilbert Gottlieb (1991: p. 7) defined as "the emergence of new structures and functions during the course of development." New structures or behaviors are the result of the bidirectional relationship between all levels of biological and experiential factors, from the genetic through to the cultural. 'Experience,' from this perspective, includes events external to the individual, such as perceptual stimulation and social interaction, but also internal events, such as the presence of neurotransmitters, hormones, and even the firing of one neuron as it influences its neighbors and itself. Functioning at one level influences functioning at adjacent levels, with constant feedback between levels. This relationship can be expressed as follows:

$$\text{genetic activity (DNA} \leftrightarrow \text{RNA} \leftrightarrow \text{proteins)} \leftrightarrow \text{structural maturation} \leftrightarrow \text{function, activity.}$$

From this perspective, all development is the product of epigenesis, with complex interactions occurring among multiple levels.

Evolved psychological mechanisms, the central tenet of mainstream evolutionary psychology, can be viewed as inherited 'messages' that, following epigenetic rules, interact over time with the environment to produce behavior (see Bjorklund et al., 2007). Because the experiences of every individual are unique, there would be substantial individual differences (i.e., plasticity) in development. Despite this, most members of a species share many features. This is because individuals inherit not only a species-typical genome, but also a species-typical environment, starting with the prenatal environment. To the extent that individuals grow up in species-typical environments similar to those of their ancestors, development should follow a species-typical pattern.

Development Is Constrained by Both Genetic and Environmental Factors

Infants are born into a complex world of sights, smells, sounds, and other people. How do they learn to figure out what is important and what is not, and, in general, to make sense of the plethora of sensations that bombard them? It was once believed that infants were born (essentially) as blank slates –

they had the general human ability to learn and, via the operations of classical and operant conditioning, learned what is relevant and what is not. This seems not to be the case. Rather, newborns are prepared by natural selection to 'expect' certain types of environments and to process some information more easily than others. From this perspective, one can talk of infants and children inheriting biases that increase the likelihood of their developing adaptive responses to their environment, with such biases and constraints *enabling* learning.

For example, from shortly after birth, infants show biases in what they like to look at and listen to, and many of these are related to other people. For instance, at birth babies prefer the voices of women to those of men (DeCasper and Fifer, 1980) and prefer to listen to the language that their mothers speak rather than to other languages (Mehler et al., 1988), biases that are surely the result of prenatal auditory experiences. Such biases should not be thought of as 'innate' in the way the term is typically used, but rather as the nearly inevitable outcomes that are constrained by how genes and experience interact in a species-typical way during early development.

An Extended Childhood Is Needed in Which to Learn the Complexities of Human Social Communities

Humans spend more of their lives as 'prereproductives' than any other mammal, something that was surely risky, especially for our ancestors who could not expect a long life. In evolutionary biology, when there are great costs associated with a characteristic (here, an extended juvenile period) there should also be great benefits. For ancient and contemporary humans, many believe that those benefits were in terms of developing a large brain capable of acquiring the skills necessary to navigate the social world (Bjorklund et al., 2005; Dunbar, 1995, 2010). The complexities of human societies are highly varied across the globe, and it takes time for children to acquire the abilities to cooperate and compete with their fellow *H. sapiens*. Humans' extended period of immaturity, coupled with a big brain that permits a social learning ability unsurpassed in the animal world, allowed our species to become as socially sophisticated as we are.

Natural Selection Has Produced Adaptations of Infancy and Childhood: Ontogenetic, Deferred, and Conditional Adaptations

If natural selection operates at all life stages, then we must look specifically at adaptations associated with infancy and childhood, rather than focusing solely on adaptations in the reproductive adult. From a developmental perspective, however, not all adaptations are created equal. Some evolved characteristics of infants and children were specifically selected to serve an adaptive function at a specific time in development, termed *ontogenetic adaptations* (Bjorklund, 1997). In contrast, *deferred adaptations* are those aspects of childhood that were selected for their role in preparing the child for adulthood (Hernández Blasi and Bjorklund, 2003). And *conditional adaptations* influence the course of children's subsequent development, depending on conditions in their immediate environment (Boyce and Ellis, 2005).

Ontogenetic adaptations emerge at different times in development and adapt the child for challenges specific to that time in life, and may disappear when they are no longer functional. That is, some aspects of infancy and childhood are not preparations for later adulthood but were selected to serve an adaptive function at specific times in development. The most obvious ontogenetic adaptations are associated with prenatal functioning. The umbilical cord, for example, delivers nutrients to and removes wastes from the fetus but is discarded at birth, as infants' entire respiratory and consummatory systems become reorganized. An example of a postnatal ontogenetic adaptation is children's physical immaturity. Research has shown that children's immature physical features (i.e., 'babyness') can help them garner nurturing behaviors from their parents. Some features of physical immaturity include heads that are proportionally large relative to their bodies, foreheads that are large in relation to the rest of the face, a small flat nose, big eyes, and short limbs (Lorenz, 1943). Adults find these features 'cute' and rate children with these features as more sociable, easier to care for, and more competent (e.g., Alley, 1981; Glocker et al., 2009; Sprengelmeyer et al., 2009) than children without them. A recent study by Sherman et al. (2009) assessed how 'cuteness' influences behavioral carefulness, the increased control of and attention to fine motor movements, after viewing immature (puppies and kittens) and mature (dogs and cats) images. Sherman et al. (2009) concluded that viewing immature faces increased fine motor abilities in adults, which the authors suggest is important for caring for a small, delicate child (see also Nittono et al., 2012). In other research, *cognitive immaturity* has also been proposed as an ontogenetic adaptation. For example, children who express some forms of immature cognition ('The sun is not out because it is mad') are rated higher on measures of positive affect by adults (e.g., cute, likable) and lower on measures of negative affect (e.g., irritable, likely to lie) than children expressing more mature cognition (e.g., 'The sun is not out because wind blew clouds in front of it') (Bjorklund et al., 2010b; Periss et al., 2012).

In other studies, young children's tendencies to overestimate their physical, social, and cognitive abilities have been shown to have some positive consequences. Research has demonstrated that preschool children overestimate their memory abilities, their intelligence, and their social standing (see Bjorklund et al., 2010a for a review). This was historically thought of as a handicap, and that children's immature cognitions would eventually develop into functional, accurate, and mature cognitions (Bjorklund, 1997; Bjorklund and Green, 1992). From an evolutionary developmental perspective, however, this poor metacognition (thoughts about the one's cognitive abilities) may hold some possible benefits (Bjorklund and Green, 1992). For instance, Bjorklund et al. (1993) assessed preschool children's pretest predictions (how well they thought they would perform a task) and posttest evaluations (how well they thought they had performed the task) of performance on a series of imitation tasks (e.g., juggling one, two, or three balls). They then correlated the accuracy of children's estimations with their performance on the Vocabulary subset of the Wechsler Preschool and Primary Scale of Intelligence. Bjorklund et al. (1993) found that verbal

IQ in the 3- and 4-year-olds was higher in children who overestimated more, while the 5-year-olds with poor metacognition (higher overestimation) tended to have lower verbal IQ scores. Thus, for younger preschoolers, being out of touch with one's abilities was related to high levels of IQ. Another study by Shin et al. (2007) found that kindergarten, first-, and second-grade children who overestimated their memory performance more on earlier trials actually had higher levels of memory recall and strategy performance on later trials than more accurate children (see also Lopez et al., 1998). These findings suggest those children's immature cognition, in this case overestimation, may in fact serve an adaptive purpose, and is not simply a 'deficiency' that children need to grow out of.

In contrast to ontogenetic adaptations, deferred adaptations are those that prepare children for life as an adult and are perhaps most easily seen through the lens of gender differences in children's behavior. For example, boys and girls tend to differ in their forms of fantasy play (see Pellegrini, 2012). Girls engage in more play-parenting and nurturing roles, while boys play power and dominance games, usually centered on aggression or domination themes. There are also gender differences in the forms of aggression used by boys and girls. Boys are more physically aggressive while girls are more relationally aggressive, revealing a female bias for social–interactional conflict and a male bias for physical conflict. This is relevant from an evolutionary perspective considering that males have, over evolutionary history, competed with other males for mates and status, while females required greater social fluency in order to acquire resources to help rear their offspring. These gender differences can be seen as antecedents for the sexual roles children will assume as adults, or would have assumed in ancient environments (*see* Human Mate Choice, Evolution of).

Deferred adaptations are most likely to evolve when environmental conditions remain relatively stable over time. This provides children with reliable information about the environments that they are likely to encounter as adolescents and adults. However, although gross aspects of children's environments may be similar over time, and even similar to the environments experienced by ancestral children, many aspects of children's environments cannot be anticipated by natural selection. Some children may be born into resource-rich environments, whereas others may be born into resource-poor environments, along with the stresses associated with such environments. Children need behavioral and cognitive flexibility in order to direct their development in anticipation of adult environments. According to Belsky et al. (1991: p. 650), "a principal evolutionary function of early experience – the first 5 to 7 years – is to induce in the child an understanding of the availability and predictability of resources (broadly defined) in the environment, of the trustworthiness of others, and of the enduringness of close interpersonal relationships, all of which will affect how the developing person apportions reproductive effort." In other words, children need to be sensitive to environmental conditions early in life and adjust some aspects of their physical and psychological development in anticipation to what their future environment is apt to be in all likelihood.

Thus natural selection should favor plasticity and sensitivity to local environments, and this often takes the form of conditional adaptations. Boyce and Ellis (2005) defined conditional adaptations as "evolved mechanisms that detect and respond to specific features of childhood environments – features that have proven reliable over evolutionary time in predicting the nature of the social and physical world into which children will mature – and entrain developmental pathways that reliably matched those features during a species' natural selective history" (p. 290).

Perhaps the most studied topic from this perspective is the rate at which children (especially girls) attain puberty and their future adult mating strategies as a function of their early rearing environment. Belsky and his colleagues (1991) argued that children's early environments are good predictors of what their later environments will be like. An adaptive reproductive strategy ('adaptive' from an evolutionary perspective, not necessarily from the point of view of mainstream society or of mental health professionals) for children growing up in high-stress, low-resource, and unpredictable environments is to reproduce early and often, because it is substantially less likely that any one child will have the requisite resources needed to meet his or her reproductive (evolutionarily driven) goals. The opposite pattern would develop for children growing up in more predictable and supportive homes, with their most adaptive strategy being to postpone reproduction and to invest heavily in children. Nearly two decades of research has essentially confirmed this hypothesis, finding relationships between various types of socioemotional stress measured during childhood and the age at which girls attain menarche and the particulars of their subsequent sexual behavior (see Belsky, 2007; Del Giudice, 2009; Ellis, 2004, for reviews).

Applying Evolutionary Developmental Psychology to Mental Health

Although developmental psychologists were initially reluctant to incorporate evolutionary ideas into their theories and research, the role of evolutionary thinking in explaining important aspects of human development has increased over the past decade. Evolutionary theories can provide new insights into many aspects of development. One important contribution of such thinking is in the area of developmental psychopathology (see, e.g., articles in Ellis and Bjorklund, 2012; Ellis and Boyce, 2011).

The Mental Health Model

The current dominant scientific paradigm for explaining the relationship between high-risk environments and subsequent mental health could be referred to as the *mental health model*, or the *diathesis-stress model*, which assumes that high-risk environments adversely affect children's well-being, promoting *disturbances* in development, even if not clinical disorders per se, and contend that certain individuals are predisposed to develop psychopathologic conditions when exposed to stressful environments. According to this model, supportive environments tend to produce 'good' developmental

outcomes, such as good health, happiness, secure attachment, high self-esteem, emotional regulation, and educational success, whereas negative, stressful environments promote 'bad' developmental outcomes, such as illness, insecure attachment, behavioral problems, drug use, alcoholism, conduct problems, depression, early pregnancy, and limited education. This has led researchers to focus on the deleterious effects of familial and ecological stressors on mental health outcomes (e.g., adolescent onset of psychopathology). Dysfunctional behavior in childhood and adolescence is seen as the natural consequence of exposure to harsh, unpredictable, or uncontrollable socioecological contexts. As such, the mental health model emphasizes *costs* and largely ignores any *benefits* of children's responses to their life situations, making it difficult to explain children and adolescents' motives for their behavior. This leads to the view of children's reactions (e.g., conduct disorder in childhood, adolescent risk behavior) as inherently pathological, thereby requiring preventive interventions.

Evolutionary Developmental Psychological Models of Mental Health

In contrast, an *evolutionary developmental perspective* assumes that natural selection designed the developing brain to respond to different environmental contexts – good and bad – in an adaptive manner. When children encounter stressful environments, therefore, it does not disturb their development so much as it *directs* or *regulates* it toward strategies that are adaptive under stressful conditions – even if those strategies are currently harmful in terms of the long-term welfare of the individual. As stated by Ellis and his colleagues (2012: p. 600), "The evolutionary model posits that natural selection shaped our neurobiological mechanisms to detect and respond to the fitness-relevant costs and benefits afforded by different environments. Most important, these responses are not arbitrary but function adaptively to calibrate developmental and behavioral strategies to match those environments."

These adaptations may well be harmful in terms of the long-term welfare of the individual and society as a whole, but they are well designed to cope with the immediate circumstances. In some cases they are deeply ingrained in our psychology and physiology, based on many thousands of generations of genetic evolution. In other cases they are culturally ingrained, which does not make them any less compelling. Either way, when we understand the local sense in which children and adolescents' responses to high-risk environments are adaptive, a different agenda for research and intervention emerges, as compared with the mental health model.

Using an example summarized earlier, children growing up in high-stress environments with minimal resources and unstable homes would benefit (from an inclusive-fitness perspective) by reproducing early and often, rather than waiting to reproduce (as society would prefer), because it is unlikely that they will have the necessary resources needed to succeed in the long term. It is important to note that just because children and adolescents are adapting to harsh environments does not imply that these are ideal situations or that there are no costs. Harsh environments certainly have costs, sometimes even resulting in death, but this viewpoint recognizes the possible benefits of high-risk behaviors. Avoiding this naturalistic fallacy (i.e., thinking that 'natural' is 'good' or 'justifiable'), one can see how children adapting to high-stress environments allows them to make the best of a bad situation, although it may be seen as a negative outcome by conventional societal standards.

In this vein, several theorists have proposed specific evolutionary models based on the idea that conditional adaptations underpin development of *contingent* survival and reproductive strategies and thus enable individuals to function competently in a variety of different environments. For example, W. Thomas Boyce and Bruce Ellis' (Boyce and Ellis, 2005; Ellis and Boyce, 2008; Ellis et al., 2005, 2011) theory of *biological sensitivity to context* attempts to explain the adaptive relation between early life experience and stress reactivity. It proposes that early environment helps in priming the future stress reactivity, and that early experience with stress interacts with individual differences in aspects of children's personalities, sometimes producing adaptive long-term outcomes and sometimes even producing maladaptive long-term outcomes, depending on the quality of environment children live in. Both genetic dispositions and early experience influence how readily young organisms respond to events in the environment (that is, how sensitive they are to context), which in turn affects their long-term reactions to stress. Those individuals who are especially biologically sensitive to changes in the environment may gain special benefits or experience special deficits from extreme environments, relative to less-sensitive (and more stable) individuals; that is, sensitive individuals are impacted by their environment both *for better and for worse*. This contrasts with the mental health model's exclusive focus on possible negative implications of difficult environments.

This 'for better or for worse' phenomenon can be seen in research from Boyce and his colleagues (1998) with rhesus monkeys. Boyce et al. (1998) measured biological reactivity to novel experiences in a troop of rhesus monkeys living in a low-stress environment. Some monkeys were highly reactive to novel experiences, showing elevated cortisol levels, whereas others were less reactive. Furthermore, an examination of injuries over the course of a year indicated slightly more injures for animals classified as low in reactivity than those classified as high in reactivity. The monkeys then experienced a highly stressful period of confinement to a 1000-square-feet building. The rate in injuries between the high- and low-stress environments did not vary for the monkeys classified as low in biological reactivity. However, rates of injuries skyrocketed for the high-reactive monkeys. Whereas these monkeys had the lowest rate of injuries in the low-stress environment, they had the highest rate in the high-stress environment.

In a study with human children, Boyce and his colleagues (1995) measured the incidence of respiratory infections in 3- to 5-year-old children who were classified as either low or high on the basis of cardiovascular and immunologic reactivity. The incidence of respiratory infection for low-reactive children was about the same regardless if they came from low- or high-stress homes (a little less than three infections per 3-month period) (see also Obradović et al., 2010). In contrast, high-reactive children had the lowest

incidence of infections if they came from low-stress homes (slightly over two infections per 3-month period), but the highest rate if they came from high-stress homes (about 3.5 infections per 3-month period).

In describing high-reactive and low-reactive children, Boyce and Ellis (2005) used the metaphor of the *orchid* and the *dandelion*. Stemming from a Swedish idiomatic expression, *maskrosbarn*, the dandelion child refers to resilient children who are able to thrive in both negative and positive environments. In contrast, the *orkidebarn* refers to the orchid child, described as the "context-sensitive individual, whose survival and flourishing is intimately tied, like that of the orchid, to the nurturant or neglectful character of the ambient environment. In conditions of neglect, the orchid promptly declines, while in conditions of support and nurture, it is a flower of unusual delicacy and beauty" (Boyce and Ellis, 2005: p. 284).

In a related theory, Jay Belsky and his colleagues (Belsky, 2000, 2005, 2007; Belsky et al., 2007) proposed that some children are more sensitive to individual differences in parenting than others, or differentially susceptible to environmental influences. According to *differential susceptibility theory*, when environments are unpredictable, children who are easily able to adapt to a wide range of contexts (that is, who are highly responsive to differences in parenting behavior) will be able to adjust to novel, often less-than-optimal, environments (for example, father absence, insensitive parenting). They will also do particularly well in enriched environments, those providing better-than-average support, resources, and opportunities. Other children, however, are more stable and less influenced by extreme environments. Parents can hedge their bets, so to speak, by producing both types of children, some who will be receptive to change and others who will thrive in the 'expected' environment. Belsky believes that whether children are sensitive to parenting or not is primarily a function of genetics. Who are the children most sensitive to parents' endeavors? A number of researchers have shown that highly fearful, anxious, and 'difficult' children are more influenced by parental behavior (for example, maternal style of discipline) than less-anxious or 'average' children (Gilissen et al., 2008; Kochanska, 1993), as are infants with difficult temperaments (Stright et al., 2008; see Belsky, 2005; Belsky and Pluess, 2009).

In summary, the mental health model, the currently dominant scientific paradigm, is unable to fully explain the relationship between high-risk environments and subsequent mental health as it focuses exclusively on costs of risky actions and does not account for any of the potential evolutionary benefits that may result from engaging in such behaviors. The evolutionary developmental perspective, however, contends that natural selection has shaped children to be able to respond to both positive and negative environments in an adaptive manner. Children who are most susceptible, the orchid children, will thrive in supportive, stable environments, but will have greater adverse effects in less than ideal environments as well. Less susceptible children, the dandelions are more stable and are less likely to be influenced by external factors, irrespective of whether they are good or bad.

The Evolutionary Developmental Model and Risky Adolescent Behavior

Application of these differential sensitivity models can be seen in examinations of risky behavior in adolescents. Adolescents are more likely than any other population to engage in risky behaviors, such as sexual promiscuity, crime, and aggression (Steinberg, 2008). The mental health model would categorize these behaviors as maladaptive outcomes stemming from a negative environment and genetic disposition. This perspective, according to Ellis et al. (2012), only captures the downside of risk without considering why people take risks. Risky behaviors are not maladaptive if the expected benefits outweigh the expected costs.

Adolescent behavior, including risky behavior, should, according to the evolutionary developmental model, be examined for potential fitness benefits. It is important to note again the distinction between risky and maladaptive behaviors; risky behaviors may result in harm to the individual, but may still serve an evolutionary (i.e., fitness) purpose. Given this, however, risky adolescent behaviors still frequently produce negative consequences for the individual and the society as a whole and should therefore be examined in an attempt to minimize them. According to Ellis et al. (2012), viable solutions for interventions require understanding why adolescents engage in risky behaviors, rather than just categorizing them as negative and maladaptive.

Ellis et al. (2012) argue that adolescence serves as a critical period for individuals to develop and master their social milieu and reproductive strategies. Puberty is characterized by specific maturational changes such as the emergence of primary and secondary sexual characteristics, marked increase of appetite, height, and weight, increase in sensation-seeking, high-arousal experiences, and increases in peer aggression and parental conflict. Also apparent is the emergence of sexual motivation and desire to develop and maintain opposite-gender relationships. These changes correspond with many of the behaviors adolescents exhibit: the development of sexual characteristics makes an individual more attractive to the opposite gender, which corresponds to the increase in sexual drive and desire for high-arousal experiences. Higher levels of aggression and parental conflict help adolescents develop autonomy and attain social dominance among their peers, which helps explain the higher-stakes competition that occurs in adolescence over mates (or boyfriends and girlfriends), social status, and friendships.

Relative to adulthood, the adolescent years are associated with higher rates of depression, eating disorders, alcohol and drug use, violence, and sexual promiscuity. Ellis et al. (2012) argue that social feedback is particularly crucial to adolescents, with natural selection favoring increased emotional, behavioral, and neurobiological responses to activity within the social realm. For example, Chein et al. (2011) suggest that the presence of peers influences activation in the adolescent brain, but not the adult brain. Using functional magnetic resonance imaging, Chein et al. (2011) measured brain activity in adolescents and adults as they made decisions in a simulated driving task across two conditions. The first condition had the participant in the simulated driving task alone, whereas the second condition informed the participants

they were being watched by their peers. During the peer-observed condition, adolescent, but not adult, brains exhibited activity in the reward centers of the brain (ventral striatum and orbitofrontal cortex), which predicted subsequent risk-taking behaviors. Consistent with Ellis et al.'s (2012) position, these results suggest that peer influence plays a greater role in regulating social behaviors, particularly risk-taking behaviors, more during adolescence than in adulthood.

Of course, not all adolescents engage in risky behavior to the same extent. The mental health model has been successful in identifying some of the specific environmental conditions that generally produce stressful or supportive environments, which in turn are associated with adolescents' tendencies to engage in risky behaviors or poor mental health outcomes. Differences along the continuum of parental sensitivity, parental harshness, marital quality, parental mental health, and socio-economic status are just a few of the factors that the mental health model examines in order to understand behavioral outcomes. But as Ellis et al. (2012: p. 608) state, the mental health model has not been explicitly informed by evolutionary theory and, consequently, has not focused on or delineated *basic dimensions* of environmental stress and support that guide conditional adaptation. According to this position, guided by *life history theory* – which postulates that important developmental events in an animal's life are shaped by natural selection to promote inclusive fitness (*see* Fertility Theory: Embodied-Capital Theory of Life History Evolution) – individuals make trade-offs that prioritize resource and energy expenditures, such as reproduction (mating, parental investment) and bodily protection (predator defense, immune function), so that greater investment in one domain occurs at the expense of investment in other domains. Life history theory states that individuals will select a strategy that optimizes their trade-offs over the life course. These strategies lie on a slower–faster life continuum. Earlier pubertal timing, more sexual partners, earlier age of reproduction, more offspring with lower parental investment, and more risky behaviors typically characterize a faster life history strategy. A slower life history strategy, on the other hand, is characterized by slower rates of development, delayed age of first sexual encounter and reproduction, fewer offspring with higher parental investment, and exhibiting fewer risky behaviors (see Figure 1).

Figure 1 Faster versus slower life history strategies. Reproduced from Ellis, B.J., Dahl, R.E., Del Giudice, M., Dishion, T.J., Figuerdo, A.F., Gray, P., Hawley, P., Jackson, J.J., Jacobs, W.J., Volk, A.A., Wilson, D.S., 2012. The evolutionary basis of risky adolescent behavior: Implications for science, policy, and practice. Developmental Psychology 48, 598–623.

An Evolutionary Life History Framework: Harshness and Unpredictability

Recent research following these models has elaborated on children's sensitivity to context by going beyond the study of harsh environments and also examining the unique predictive value of variations in environmental predictability as well (Belsky et al., 2012; Ellis et al., 2009; Simpson et al., 2012). Ellis et al. (2009) proposed an evolutionary life history framework, stating how different environmental conditions early in development affect the fast versus slow life history trajectories, specifically the influence of harshness and early unpredictability. Ellis et al. (2009) defined harshness as age-specific rates of morbidity and mortality, predictably measured by socioeconomic status (SES); they defined unpredictability as the fluctuations of harshness across development. Unpredictability is measured by indicators such as frequent residential changes, parental divorce, and remarriage. Ellis et al. (2009) proposed that each of these environmental factors should uniquely contribute to differential outcomes in life history strategies. For example, in one recent study, family social disadvantage (harshness) predicted deviant, often criminal, behavior and the number of children one had in early adulthood (Dishion et al., 2012). Other research has shown that the predictability of a child's early environment can have an independent effect on a child's developmental trajectory. For example, Belsky et al. (2012) tested a model proposing that higher environmental harshness and higher levels of unpredictability in the first 5 years of the child's life will independently predict an accelerated life history trajectory. They found that unpredictability of a child's environment in the first 5 years is a more direct predictor of having a larger number of sexual partners, a signal of an accelerated life history strategy, at 15 years of age, while early harshness had a more indirect effect.

Simpson and his colleagues (2012) extended this line of research by looking at multiple life history variables, as opposed to just the number of sexual partners, and extended the outcome measure (number of sexual partners) to the age of 23. They also examined whether predictability and harshness are more influential on development when occurring in early (prenatal to the stage of 5-year-old children) vs later childhood (6- to 10-year-old children). Supporting the results in Belsky et al. (2012), they reported that exposure to harshness and

(especially) unpredictability in the first 5 years of childhood significantly and independently predicted an accelerated life history trajectory by having higher levels of aggression and incidences of delinquent behavior, more sexual partners, and higher likelihood of being associated with a criminal act. As expected, exposure to harshness and unpredictability in later childhood (6- to 10-year-old children) were not significant predictors of these outcomes.

If the environment is unstable and fluctuates often, it may be more beneficial for the individual to develop a faster life history strategy, reproducing faster and more often, in anticipation that future environments will be unpredictable. Alternatively, if one's early environment is stable, this is a good indication that future environments will also be stable, and a slower life history strategy would be more beneficial in the long run. From an evolutionary perspective, adolescents exhibiting risky behaviors, sexual promiscuity, and early reproduction are exhibiting adaptive behaviors that are best suited for their environmental context. Exactly these patterns have been observed in several recent studies (Ellis et al., 2009; Simpson et al., 2012), independent of measures of harshness, finding strong support for the evolutionary developmental models.

The Evolutionary Developmental Model and Antisocial Behavior

An evolutionary developmental perspective can also shed light on antisocial behaviors, such as bullying or stealing. Research by Hawley (1999, 2002, 2003) suggests that behaviors that would normally be characterized as antisocial are often quite successful in attainting resources for individuals exhibiting them, at least in some environments. Hawley (1999) posited three classes of children with respect to resource control: prosocial controllers, coercive controllers, and bistrategic controllers. Prosocial controllers gain and maintain access to resources by cooperating in a group, are socially skilled, and are typically friendly and well liked by peers. Coercive controllers are strictly aggressive in their attainment of resources. They tend to be impulsive, aggressive, and socially rejected. In contrast, bistrategic controllers use both prosocial/cooperative and antisocial/coercive strategies to attain and maintain resources, but tend to be socially savvy, attractive social partners, who also exhibit aggression and bullying similar to that of coercive controllers.

From this perspective, aggressive behaviors, although disruptive in a classroom and potentially leading to injuries, especially among adolescents, serve to obtain resources, access to mates or friends, and achieve social dominance (Sijtsema et al., 2009; Veenstra et al., 2010), with some children using aggressive behaviors strategically in combination with prosocial behavior. Furthermore, the adaptive benefits of bullying are evident by data that children identified as bullies tend to date at younger ages and engage in more dating activities than their nonbully counterparts (Connolly et al., 2000; Faris and Felmlee, 2011; Gallup et al., 2011).

In summary, aggression may have evolutionary benefits in attaining resources and social dominance, and ultimately, mating opportunities. The fact that aggressive behavior, often in the form of bullying, frequently has some benefits for children and adolescents in no way condones such behavior, but rather provides insights into why some intervention programs are destined to failure and others have a chance of succeeding.

Conclusion

Darwin's theory of natural selection is the driving force for modification and survival over time. Evolutionary explanations have been widely used to examine adult behavior and psychology; however, the field of evolutionary developmental psychology contends that natural selection acts throughout ontogeny and not simply only in adulthood. Individuals must survive the often-hazardous periods of infancy and childhood before reaching adulthood, suggesting that any adaptations that increase the chance of surviving to adulthood during the early stages of life would certainly be favored by natural selection.

An evolutionary approach to infancy, childhood, and adolescence provides researchers and practitioners with new insights with which to view both typical and atypical development. In particular, when 'problematic' behavior, such as risk-taking or aggression, is observed in children or adolescents, an evolutionary approach causes one to ask "What's in it for the child?". That is, although bullying or sexual promiscuity in children and adolescence, for example, are clearly behaviors that society has every right to want to minimize, an evolutionary developmental perspective recognizes that these behaviors may provide some adaptive value for some children in some specifiable contexts.

Applying evolutionary ideas to help understand both typical and atypical development does not mean that the other accounts (e.g., learning, social, cognitive) are unnecessary. Rather, an evolutionary perspective supplements other approaches to understanding development and, in the end, produces a more complete, and from an application perspective perhaps more useful, account of development. In fact, one might modify once again Dobzhansky's famous statement and say that "nothing in childhood and development make sense exception in the light of evolution" (cf Konner, 2010).

Abstract

There are several ways to incorporate evolutionary concepts into economic thinking. This article reviews the most important transfers of this kind into evolutionary economics. I broadly differentiate between approaches that draw on an analogy construction to the biological sphere, those that make metaphorical use of Darwinian ideas, and avenues that are based on the fact that other forms of – cultural – evolution rest on foundations laid before by natural selection. It is shown that an evolutionary approach within economics informed by insights from cognitive science, evolutionary biology, and anthropology contributes to more realistic models of human behavior in economic contexts.

Introduction

Evolutionary economics is a paradigm for explaining economic change. In principle, there are several ways to incorporate evolutionary concepts into economic thinking to reach this explanatory goal. This problem has triggered an ongoing conceptual-methodological debate in the evolutionary economics community (see Knudsen, 2004; Hodgson and Knudsen, 2006; Cordes, 2006; Witt, 2003). In this article, I broadly differentiate between two potential channels of concept transfer. First, economics can be turned into an evolutionary science by introducing aspects of Darwin's explanatory model of biological evolution (*see* Darwinism) to economic theory via the construction of analogies or the metaphorical use of Darwinian ideas. Second, Darwinian concepts are relevant for explaining the basis on which economic evolution rests. On the one hand, biological evolution defines the long-term constraints on human-made economic evolution. On the other hand, innate dispositions of humans that have been shaped by natural selection earlier in humans' phylogeny define the cognitive foundations on which economic evolution rests. We call this second way of incorporating evolutionary concepts to economics a 'naturalistic approach.' Common to both approaches is the criticism of the widespread tradition in economics to derive human behavior from abstract principles without proper reference to insights from the evolutionary sciences.

Analogies to the Biological Sphere and the Metaphorical Use of Evolutionary Concepts in Evolutionary Economics

So-called neo-Schumpeterians within the evolutionary economics camp consider the concept of selection (*see* Adaptation, Fitness, and Evolution; Microevolution) as a core element of evolutionary economics. Selection processes, they argue, act on the diversity of behaviors and entail behavioral adaptations of agents who are only boundedly rational (i.e., their rationality is limited by the information available to them and by their particular cognitive and time constraints). This fact prevents optimal adaptation to external environments by the agents themselves. Nelson and Winter's (1982) as well as Metcalfe's (1994) approaches belong to this strand of thinking. Although the former relies on a largely metaphorical import of biological concepts to economics, the latter draws on a more direct application of a model of natural selection to economic competition. Finally, the idea of a generalized Darwinism is based on a close analogy to the biological realm and claims that a set of abstract Darwinian principles also can be applied to economic evolution.

Nelson and Winter's Concept of Organizational Routines

Nelson and Winter (1982) offer an evolutionary theoretic view of the firm that is inspired by previous works of Schumpeter (1934), Penrose (1959), Simon (1955), and Cyert and March (1992). Their theory is based on the notion of organizational routines and draws on a metaphorical use of the Darwinian theory of natural selection. Their behavioral assumptions deviate substantially from those of standard economics: Firms are not profit maximizers but follow rather rigid rules or routines, and agents, including managers, are only boundedly rational. For instance, there are two types of search rules for finding an improved technology: First, innovating by conducting a local search close to the currently applied technology, whereby the probability of success decreases with an increasing distance to the actual technology. Second, by imitating technologies of competitors in one's industry by observational learning, firms can adopt new technologies. In this context, an erroneous estimation of the new technology's input coefficients by managers is always possible.

Routines define the firm's core capabilities and are defined as regular patterns of deliberating and acting in organizational processes. They are partly unconscious or tacit and are questioned only in the case of insufficient performance ('satisficing behavior,' see Simon, 1955). Routines enable coordinated behavior (behavior of others can be anticipated) while avoiding great decision effort on the part of cognitively constrained individuals. There is a hierarchy of organizational routines: lower order organizational skills and higher order decision procedures. Routines serve as a firm's 'memory' and are based on metaindividual, partly implicit shared knowledge. On the one hand, routines allow for fast and effective behavior in well-defined situations. On the other

 http://dx.doi.org/10.1016/B978-0-08-097086-8.81019-3

hand, there are constraints in modifying, replicating, and imitating routines, which might entail dysfunctionality in changing business environments and organizational inertia.

Moreover, to innovate in a dynamic Schumpeterian environment, firms choose different strategies and have different core capabilities (e.g., in research and development), that is, there is variety within the population of firms, which is a prerequisite for market selection to take place. The focus is on competition between heterogeneous firms instead of a representative firm or macroproduction functions. In this context, firm strategies are as much a matter of, for example, faith of top management or company tradition, as they are of calculation, and there is no reason to argue a priori that firm commitments are optimal. Nelson and Winter's theory involves the general Darwinian principles (*see* Darwinism) of variation, retention, and selection: Variation is introduced by firms developing new routines, retention is facilitated by stable routines, and selection is represented by competition between firms endowed with varying sets of routines. The latter process determines the differential dissemination of routines, that is, modified 'gene frequencies' in the 'gene pool,' via differential firm growth through the reinvestment of profits. Routines are considered as a firm's genes and a population of firms represents an industry's 'gene pool.' Diversity in firm behaviors tends to be eroded by market selection.

Nelson and Winter's formal approach is based on a replicator dynamic – a concept stemming from population genetics – that describes how profitable firms' capital stocks grow and unprofitable firms' capital stocks shrink. They then carry through a series of computer simulations of their model of firm competition. The final modeling aim of Nelson and Winter is to reproduce the results of the neoclassical (Solowian) growth model in a formal approach that includes competition via innovation and imitation. Their approach amounts to a revival of Schumpeterian ideas in combination with a biological metaphor. Moreover, it provides an alternative growth model that is based on a more realistic description of firm behavior and competitive processes.

Metcalfe's Use of the Replicator Dynamic

Selectionist models (*see* Adaptation, Fitness, and Evolution; Microevolution) analogous to phylogenetic biological evolution are prominent in many works in the field of evolutionary economics. One prominent example is the work of Stanley Metcalfe (1988, 1994). He analyzes the diffusion of innovation in an economy with the help of a replicator dynamic (analogous to 'Fisher's principle' in population genetics). In general, diffusion analysis is concerned with how the economic significance of a new technology changes over time, which is an aspect of structural change: new technologies are integrated into the economy and impose changes upon its structure. Metcalfe shows that the relative profitability of competing technologies or innovations is important, not their absolute profitability, and that the former will change during the diffusion process.

His basic argument relies on technological variety across firms as the basis for competitive advantage and a determinant of how rival technologies diffuse relative to one another. The rate of diffusion of an innovation is linked directly to that innovation's distance from average-practice technology, that is, economic variety is correlated with the pace of selection: The change of a technology's market share is proportional to the distance between its own unit cost and population average unit cost. By this process, the lowest cost, best-practice technology is brought to dominance (other technologies dropping in relative terms to zero). Selection works on economic variety at a pace that is directly proportional to economic variety at any point in time, a phenomenon known as the 'distance from the mean principle' that underlies many selection processes. In the course of this process, selection destroys the variety on which it depends. There is, however, an endogenous relation between selection and variety generation: Selection will, via induced technological creativity, generate new variety – as is assumed in Schumpeterian economic development.

Metcalfe's model reproduces empirically observable stylized developments of variables that also have been the subject matter of neoclassical growth models (e.g., capital accumulation in Solow-type growth models), industrial economics (e.g., within-industry competition processes), or diffusion theory (e.g., the dominant stylized fact that the usage of new technologies over time typically follows an S-curve). Diffusion phenomena, Metcalfe argues, should be treated as part of the broader picture of competition and structural change in capitalist economies because they describe the unfolding of economic structures as a consequence of variety in behavior or innovative activity. Therefore, at the root of the replicator dynamic is the notion that competition is driven by technological or behavioral variety, implying that there is no representative firm or technology and no static equilibrium.

Generalized Darwinism: Applying a Core Set of Darwinian Principles

Generalized Darwinism shows how abstract principles derived from Darwin's explanatory model of biological evolution (*see* Darwinism) can be applied to cultural evolution. In his article "Darwinism in Economics: From Analogy to Ontology," Hodgson (2002) expounded his notion of this concept (labeled here as 'universal Darwinism'): a core set of Darwinian principles that, along with auxiliary explanations specific to each scientific domain, is considered applicable to a wide range of phenomena. Hodgson argued that evolutionary aspects of the biological and the cultural spheres both involve the general Darwinian principles of variation, inheritance, and selection. Generalized Darwinism seeks to apply Darwinian principles to cultural evolution (*see* Cultural Evolution: Overview; Evolutionary Epistemology), that is, it is argued that these principles also are valid for explaining other forms of evolution. Consequently, generalized Darwinism is proposed as a broad theoretical framework for the analysis of the evolution of all open, complex systems, including economic systems. Hodgson has argued that Darwinian evolution shares these common general features with economics due to the fact that both biology and the social sciences address evolving systems. Thus, he says, Darwin's explanatory model provides a theoretical framework and ontological precepts. Hence, generalized Darwinism suggests making substantial use of Darwinian concepts, that is, the latter are not applied in a heuristic or metaphorical form only.

The intention of a generalized Darwinism is to apply Darwinian principles as a general purpose tool to various forms of evolution sharing a common ontological basis (see Hodgson and Knudsen, 2004; Knudsen, 2004; Stoelhorst, 2008). These principles – variation, inheritance, and selection – are an abstract reduction derived from Darwinian theory in evolutionary biology and, by analogy, are transferred to economics. Knudsen argued, "that an appreciation of the causal structure of neo-Darwinism may help develop a general selection theory which can be used as a basis for a development of evolutionary economics" (Knudsen 2002, p. 446). Hodgson (2002, 2003) introduced socioeconomic replicators, such as habits, routines, and institutions, which are compared with DNA and that subsequently are subject to selection. Moreover, he stated that socioeconomic replicators make copies of themselves, although imperfect ones. Proponents of a generalized Darwinism argue that abstraction removes the particular content from the specific domain in which principles apply. Hence, they maintain, the abstract principles of Darwinian evolution can be applied in different evolutionary domains.

The Naturalistic Interpretation within an Evolutionary Economics

The approaches in this section all focus on the lasting influence of humans' biological inheritance on contemporary behavior and the constraints on economic evolution set by biological evolution.

American Institutionalism: Turning Economics into an Evolutionary Science

Since their emergence during the second half of the nineteenth century, Darwin-inspired, instinct-based theories of human agency have delivered the psychological foundations of American Institutionalism (e.g., Rutherford, 2000; Asso and Fiorito, 2004). In contrast to the modern ethological understanding of the term 'instincts,' institutionalists at that time did not consider them to be more or less fixed behaviors, but as a bundle of flexible dispositions or propensities that can be suppressed or diverted (Hodgson, 2004, p. 162). Present-day cognitive scientists would speak of 'psychological dispositions' when addressing the same phenomena. This understanding of instincts as evolved, innate human dispositions by institutionalists enabled cross-fertilization between economics, evolutionary biology, and psychology. Psychologist William McDougall (1910, 1924) laid the foundation of instinct theory. He argued that, directly or indirectly, instincts are the prime movers of all human activity by determining the latter's ends. McDougall defined instincts as innate psychophysical dispositions that determine what agents perceive, pay attention to, and experience as an emotional excitement, and the impulses to act on objects in a particular manner (1910: Chapter II). Humans' intellectual apparatus then is the instrument by which these impulses seek their satisfaction. Consequently, at the beginning of the twentieth century, early institutionalists like Thorstein Veblen, Wesley Mitchell, John R. Commons, and others employed instinct theory in their analysis of economic behavior and focused especially on the interaction between instinctive motivation and intentional economic action (Mitchell, 1910; Veblen, 1914; Clark, 1918; Tead, 1918; Commons, 1920; Parker, 1920).

A path-breaking strand of this interpretation of an evolutionary economics reaches back to Thorstein Veblen. In 1898, Veblen (1898) put the question "Why is economics not an evolutionary science?" to the audience and delivered an early theoretical concept for an evolutionary approach to economics, inspired by contemporary Darwinian thought. Veblen developed a theory of institutional evolution that takes into account the cumulative nature of the cause and effect sequence of the process of institutional development. The first part of Veblen's "Instinct of Workmanship" (1914) contains the most systematic formulation of his theory of institutional change and its psychological foundations. Instincts are a key component of Veblen's theory of institutional evolution (see also Ayres, 1958).

Veblen (1919, p. 231) criticized the hedonistic, selfish, and rationalistic psychology of orthodox economics. As an alternative, he suggested a psychology based on instincts and habits that was crucially inspired by McDougall's work and integrated it into his model of institutional change (see Mitchell, 1914; Rutherford, 2001). He considered the determinants of human behavior to be the main explanatory variables and driving forces of institutional change. Thereby, behavior responds to two kinds of determinants: the basic drive of instinctive factors and the drive to conform to habits. With respect to the capacity to motivate behavior, instincts and habits are functionally equivalent. Habits, as elements of the socially approved scheme of conduct and pursuit, become proximate ends of endeavor. They may even occupy the interests of agents to such an extent that the instinctively given ulterior purpose temporarily loses influence (Veblen, 1914, p. 7). Although the formation of habits relies on evolved sophisticated forms of social learning, instincts are based directly on innate cognitive dispositions. In general, Veblen identified instincts as specific innate tendencies of the mind that have evolved in the process of adaptation of species to their environment.

Veblen's theory of cumulative evolutionary change takes the following shape (see Rutherford, 1998): The starting point of institutional change always consists of the given instinctive endowment of humans – including, for example, the instinct of workmanship that underlies technological creativity, and social instincts, such as the parental bent that aims at the welfare of the family or group, including nonrelatives. Objectives that people pursue are, in line with McDougal, a matter of instinct (Veblen, 1914, p. 3). It is by the prompting of instinct that reflection, deliberation, and technological creativity come to be employed. The established way of life making up society's material and technical conditions gives rise to corresponding habits of action as well as thought and finally institutions. The latter are supported by social sanction and are passed on through socialization. Institutions are largely "a matter of tradition out of the past, a legacy of habits of thought accumulated through the experience of past generations" (Veblen, 1914, p. 7). If the existing institutional

circumstances are not too obstructive, the instinctive nature of humans will express itself in ways that result in new technological insights, new corresponding habits of action and thought, and ultimately new institutions.

The Evolution of Institutions: Hayek and North

In a manner similar to Veblen's ideas of human nature, F. A. Hayek – as a representative of the Austrian School – assumed a core set of human instincts that evolved in the primitive tribal societies of prehistory. Hayek's theory of their exact nature is, however, much less developed than Veblen's (see Hodgson, 2007). Following Hayek, innate behavioral dispositions can be assumed to have great influence on the evolution of institutions. He stated that frugal forms of social behavior, values, and attitudes became genetically fixed during human phylogeny. His conception of instincts starts from his notion of social rules: A stratification of rules of conduct rests on genetically inherited 'instinctive' drives that are determined by 'physiological structure' (1979, p. 159f). This system of layered rules includes traditions of the past and a thin layer of deliberately added 'made' rules. Hayek also explicitly stated that humans' instinctive proclivities evolved in the course of millions of years during which the biological constitution of humans was created by natural selection. Hayek did not, however, appreciate the continuous impact of instincts on intentionality, learning, and other forms of cognition (see Hodgson, 2007).

Moreover, Hayek did not specify the exact content of humans' innate instincts and how their working keeps influencing institutional evolution. Instead, he just claimed that instincts are 'tamed and checked' by the rules of conduct and institutions of civilized society (Hayek 1960, p. 60f). In Hayek's theory of human nature, there is therefore a constant conflict between innate instincts – adapted to life in primitive societies or tribes – and the necessity to behave according to a civilized society's abstract rules. The social rules of conduct are meant to restrain the 'natural' instincts to enable the 'open society' that is based on larger and ordered groups (Hayek, 1979, p. 160ff).

Hayek also shared a strong interest in theories of cultural evolution with Veblen. They both emphasized the unique human capability for cultural adaptations through cultural learning. Moreover, they both paid extraordinary attention to group-regarding proclivities. Hayek argued that an inherent part of human nature includes the welfare of others as a condition for individual happiness (Hayek 1960, p. 78). In particular, he mentioned the instincts of solidarity and altruism, which apply to the members of one's group (Hayek 1988, p. 12 and sections 3 and 4). Furthermore, Hayek's theory of societal evolution includes the idea of a process of cultural group selection (*see* Human Cooperation: Evolution of) – an idea that also was also prominent among American institutionalism (Cordes, 2007). According to Hayek, social learning processes form a layer 'between instinct and reason' consisting of rules of conduct as basic institutions. This part of his conception of cultural evolution is akin to Veblen's notions on the role of habits. The rules of conduct, Hayek argued, can emerge as collective, unintended outcomes and then affect a society's economic prosperity, which, in turn, drives the group selection process between societies (Hayek 1979, p. 160). Existing rules of conduct have developed because the groups practicing them were more successful and displaced others (Hayek 1973). Hayek therefore claimed that beneficial institutions and ideal rules of conduct are not a result of human reason but rather spring from a cultural evolutionary process – that is, group adaptation to past experiences (1979, p. 155ff).

A naturalistically inspired theory of economic change has been brought forward by Douglass North (2005). His approach puts human cognition center stage: The driving forces of economic evolution are, he argued, human intentionality, beliefs, cognitive learning, and knowledge creation, including its subsequent dissemination via social learning. Denzau and North (1994) have provided a conceptual link between human cognition and the evolution of institutions. They have argued that to understand the constraints on human choice, one has to explore the relationship between the categories and mental models that individuals construct to make sense out of their environment, on the one hand, and the institutions that develop in historical time to order social interactions, on the other. Categories and mental models are based on individual and collective learning processes, that is, evolved capabilities of social cognition contribute to the design and the passing on of these mental frameworks.

Thermodynamics: Constraints on Economic Evolution

Another author who took up a naturalistic stance on economics is Georgescu-Roegen (1966, 1976; see also later contributions in this spirit: Gowdy (1994) or Faber and Proops (1997)). His focus was on the long-term constraints biological evolution puts on economic evolution. Georgescu-Roegen labeled his approach 'bioeconomics.' He brought forward the idea that the economic process is a continuation of the biological one that involves exosomatic instruments to obtain low entropy in addition to nature's endosomatic instruments (1966, p. 98f). The exosomatic instruments, he maintained, are a result of humans' instincts, those of workmanship and of idle curiosity – a reference to Veblen's proposed set of instincts. Georgescu-Roegen suggested concrete contents of human preferences, including biological, social, and personal wants. He showed that human beings exhibit lexicographic preferences, for example, in ethical matters, so that maximum equality of liberty takes lexicographic priority over economic well-being. These preferences violate standard assumptions concerning substitutability in choice. When referring to social instincts, Georgescu-Roegen argued that utility to an individual not only is a function of her own consumption but also considers the welfare of her community (see Gowdy and Mesner, 1998).

Moreover, starting from thermodynamics, he argued that some basic laws of physics are widely ignored by economists: The closed systems of growth models, for example, do not account for the necessary continuous inflow of low entropy from the environment to maintain economic growth. The economic process is entropic: It transforms low into high entropy (1966, p. 96f). Georgescu-Roegen insisted that economic theory be grounded in biophysical reality. By accounting for these physical laws, he introduced some

fundamental naturalistic aspects to economics: natural limitations to economic evolution. By invoking the Second Law of Thermodynamics, Georgescu-Roegen presented a constraint on all economic activity: entropic degradation. He emphasized the necessity of recognizing human agents as members of a biological species bound by biophysical processes and as social beings shaped by institutional patterns.

The Indirect Evolutionary Approach and Game Theory

Several more recent approaches claim that certain basic features of economic behavior are best explained as a result of natural selection. They account for human behaviors, such as reciprocal altruism, notions of fairness, moral behavior, and other rules of conduct that presumably have a genetic background (e.g., Hofbauer and Sigmund, 1988) (*see* Human Cooperation: Evolution of). Güth and Yaari (1992), for example, suggested their so-called indirect evolutionary approach that can be used to explain what basic wants evolutionary processes have endowed us with. They argued that wants guide behavior, behavior determines reproductive success, and the latter, as a manifestation of genetic fitness, in turn drives the evolution of wants. Individuals whose wants made them relatively more successful in acquiring and efficiently tapping scarce resources under the prevailing circumstances will have a higher number of offspring. On the condition that the offspring inherit the genetically fixed wants, those wants ultimately will be disseminated within the population, which enable an individual to cope more successfully with an environment that contains scarce resources. In this Darwinian perspective, aspects of human behavior are viewed as a product of biological evolutionary history. Furthermore, in his theory of social contract, Binmore (1998, 2001) applied a game-theoretic analysis to specify some contents of humans' preferences regarding fairness, leadership, and justice that might have evolved during phylogeny.

Another Naturalistic Endeavor: The Continuity Hypothesis

Another naturalistic endeavor in evolutionary economics starts from a 'continuity hypothesis' (Witt, 2003, p. 15f, 2004; Ruprecht, 2005; Cordes, 2006; Buenstorf and Cordes, 2008; Woersdorfer and Kaus, 2011). This departure rejects the application of abstract principles derived from Darwinism to socioeconomic evolution. At some point in time, it is argued, Darwinian evolutionary theory (*see* Darwinism) lost its power to explain human behavior. After a period of coevolution with biological evolution (*see* Gene-Culture Coevolution), cultural evolution eventually allowed forms of human behavior to emerge that entailed a strong relative reproductive success, reducing selection pressure significantly and increasing behavioral variety. Other forms of evolutionary change take place within the freedom left by the constraints of Darwinian evolution, but with different means and according to their own regularities. The foundations of cultural evolution, however, have been laid before by natural selection in the form of humans' cognitive apparatus. This establishes an ontological continuity of evolution, yet without expanding the domain of Darwinian concepts to these new evolutionary phenomena. There are other cultural, domain-specific realizations of evolutionary processes. The continuity hypothesis shows the way in which Darwinian theory can be relevant for economics: The human species is a result of natural (Darwinian) evolution; biological evolution has shaped the ground and still defines the constraints for humanmade, or cultural, evolution.

Moreover, Darwinian theory explains the origins of economic evolution in human phylogeny and fosters the understanding of the lasting influence of innate elements, dispositions, and programs on behavior. Evolutionary selection has created a set of cognitive devices that participate in generating human behavior (*see* Cognition, Evolution of). The human behavioral repertoire is the basis on which other forms of evolution rest, not least of those that are socially contingent. From this perspective, the biologically evolved foundations of learning and reasoning directly enable and affect cultural evolution. Darwinian theories of evolution therefore are suited to explain the natural origins of, for example, human learning, intentionality, and deliberative behavior, but they are ill-suited to grasp the dynamics of cultural evolution – with its own modes of transmission – that are based on these evolved cognitive capabilities.

Among other things, a naturalistic approach that includes a set of evolved cognitive dispositions can account for the motivational underpinnings of human behavior within organizations (Nicholson and White, 2006; Langlois, 2003). Several naturalistic contributions are dedicated to an analysis of the evolution of business cultures that offer a behavioral enrichment of the theory of the firm (e.g., Witt, 1998; Cordes et al., 2008; Cordes et al., 2010). Some of these papers use formal models of cultural evolution that stem from anthropology (Cavalli-Sforza and Feldman, 1981; Boyd and Richerson, 1985) (*see* Cultural Evolution: Overview; Cultural Evolution: Theory and Models). It is shown that what successful firms do better than markets – besides economizing on transaction costs – is to establish a cooperative regime among its employees that 'crowds in' desirable behavior based on humans' unique evolved group-regarding social predispositions – behaviors that go beyond the self-regarding concerns emphasized in traditional economic and biological theory (e.g., Gintis, 2007). In this context, the theory of gene-culture coevolution serves as a central tool in this analysis (Boyd and Richerson, 1980; Richerson and Boyd, 2005) (*see* Gene-Culture Coevolution). It shows how nonselfish, cooperative human traits have evolved in humans' past and how they take effect in contemporary behavior (e.g., Henrich, 2004; Gintis et al., 2005). Moreover, several of these contributions tackle the task of understanding how entrepreneurs and other business leaders can actively shape behavior within a firm as prominent role models in cultural learning and how this affects firm performance and size – a cognitive dimension that is neglected in both transaction cost economics and the theory of the firm more generally (Witt, 2007).

The continuity hypothesis has been applied to several other areas in economics. A naturalistic concept of wants inspired by behavioral theory and cognitive psychology, for example, can explain the origins and development of – innate and learned – wants people pursue. Moreover, it is suited to grasp changes in wants, that is, to account for the fact that preferences are not constant (Witt, 2001; Ruprecht, 2005; Schubert, 2012).

Consumer behavior also has an essential role to play in any transition toward a more sustainable economy: 'green' consumption patterns, for example, can spread within a population via processes of social learning that are based on, as well as influenced by, evolved cognitive capabilities (see Buenstorf and Cordes, 2008; Woersdorfer and Kaus, 2011).

Conclusion

There are different possibilities for how Darwinian concepts can be harnessed to further develop economic theory. This article has presented approaches within evolutionary economics that are based on analogy to the biological sphere, concepts that draw on a merely metaphorical use of Darwinian ideas, and some avenues that argue that the Darwinian theory of biological evolution is relevant for the social sciences in a very basic sense: The human species is, after all, a result of natural (Darwinian) evolution and all other forms of cultural evolution rest on these foundations. In general, an evolutionary approach within economics informed by insights from modern cognitive science, evolutionary biology, and anthropology can be assumed to contribute to the development of more realistic models of human behavior in economic contexts (see Hodgson, 2004: Chapter 19).

Abstract

Traditionally, epistemology concerns justifying beliefs. What right do we have to think that our beliefs are true? Evolutionary epistemology is a form of naturalized epistemology. In naturalized epistemology, the justification provided turns on an appeal to something about the natural world, in this case the evolutionary process. Organisms that do not react appropriately to their environments are not likely to survive to reproduce. Evolutionary epistemology began as both epistemology and evolutionary. Evolutionary epistemology was 'epistemology' in the sense that it was designed to justify certain basic beliefs that people hold. Evolutionary epistemology was 'evolutionary' in the sense that it was based on evolutionary theory as a biological theory. The reason that our knowledge of the world of our experience is reasonably good is that our sense organs have been honed by natural selection, and the results of this honing are programmed into our genes. The early versions of evolutionary epistemology were gene based; that is, the relevant knowledge was programmed into our genes and thus passed from generation to generation. Things like behavior were viewed as phenotypic characteristics.

Traditionally, epistemology concerns justifying beliefs. What right do we have to think that our beliefs are true? Evolutionary epistemology is a form of naturalized epistemology. In naturalized epistemology, the justification provided turns on an appeal to something about the natural world, in this case the evolutionary process. Organisms that do not react appropriately to their environments are not likely to survive to reproduce. In some organisms this reaction can appropriately be termed 'knowledge.' Those organisms that are better at learning about their environments (which includes other organisms) are more likely to survive to reproduce than their less adept congeners. Thus, knowledge of those features of the environment that are relevant to survival and reproduction is to some extent justified. *Homo sapiens* as a species depends for its survival on playing the knowledge game better and more extensively than any other species. Evolutionary epistemologists propose to justify at least some of the beliefs that human beings hold by reference to survival value (for the most seminal paper in evolutionary epistemology, see Campbell, 1974).

Gene-Based Evolutionary Theory

In order to understand evolutionary epistemology, one must understand evolution, in particular the distinction between genotypes and phenotypes (*see* Genotype and Phenotype). The genotype of an organism consists in the sequence of bases in its DNA, or rarely, in its RNA. Everything else is part of its phenotype, from its blood type to its behavior. Variations in the genotype of an organism lead, through embryological development, to different phenotypic traits. These genetic variations are caused, totally caused. Among these causes are unequal crossover, increased temperature, and the presence of numerous mutagens. However, to count as Darwinian evolution, no correlation must exist between the variations an organism might need and those it might get; for example, it cannot be 'Lamarckian.' For Lamarckian evolution to occur, some feature of an organism's environment must change the phenotype of that organism in such a way that it is better adapted to the environmental feature that produced this change in the first place. This phenotypic change must then somehow be transmitted to the organism's genes to be passed on to subsequent generations via the genetic material. A mother dog giving fleas to her puppies does not count as Lamarckian inheritance.

Some of the traits exhibited by an organism make it better able to survive and reproduce. As a result, the genes that code for these traits are passed on differentially from generation to generation. However, as organisms become better-adapted to their environments, their environments frequently move out from under them. A few species succeed in surviving through the millennia largely unchanged, but most survive only by evolving. One feature of gene-based selection in biological evolution is that it can occur quite rapidly, as in viruses and bacteria, or quite slowly, as in most larger animals. However, in every case of Darwinian evolution, the relevant traits are inherited literally via the genetic material. Initially, the 'units' used in evolutionary biology were traits because evolutionary biologists had no access to the genetic material. As this access has increased, traits have been replaced by genes as units of inheritance. Unfortunately, the genetic material can be divided up in numerous ways. As a result, biologists concentrate on the 'information' contained in the genetic material.

Advocates of evolutionary epistemology in its most literal sense argue that the preceding story equally applies to some behavioral traits and predispositions. These traits and dispositions are as much phenotypic traits as are hair texture and skin color. Knowledge of the world in which organisms live gets programmed into an organism's genes. For example, fear of heights and the sucking reflex are in some sense programmed into the genes of human beings. The evolution of behaviors and behavioral predispositions has all the usual characteristics of gene-based biological evolution. As traits, behaviors can be adaptive. The inheritance involved is genetic, strictly Darwinian, not Lamarckian, and it can occur at a variety of rates from very slow to very fast.

[†] Deceased

The majority of epistemologists are not very impressed with evolutionary epistemology, in part because it is naturalistic, and only normative epistemologies are worth the title of epistemology. But a second weakness is that the only beliefs that evolutionary epistemology in this strict sense can even purport to justify are beliefs about entities and processes that the organism can perceive. Evolutionary epistemology might lend some justification for how human beings distinguish species of large organisms, but it cannot justify any beliefs that we have about the millions of tiny microorganisms that fill every nook and cranny of the world, let alone quantum indeterminacy.

Individual Learning

In 'eusocial organisms,' such as bees and termites, nearly all of the behaviors exhibited by these creatures evolved in a strictly Darwinian fashion. Relatively little learning takes place in the span of a single generation. But many organisms can learn from interacting with their environments. In a second form of evolutionary epistemology, knowledge does not get programmed into our 'genes,' but into our 'brains.' Gene-based selection in biological evolution can handle features of the environment that change relatively slowly, e.g., changes in temperature resulting from continental drift, but some changes are so rapid that organisms with longer generation times cannot adapt to them. One solution to this problem is the evolution of the 'central nervous system.' Organisms with highly developed central nervous systems can learn about their environments and react to changes in them with greater speed. This information does not get programmed into an organism's genes but into its brain. 'Operant learning' is the simplest form of individual learning. Each kind of organism has a range of behaviors that it tends to emit spontaneously. Feedback from its environment increases or decreases the frequency of these behaviors. Sequential environmental responses shape the behavioral repertoires of these organisms.

The preconditions for operant learning are certainly programmed into the genes of those organisms that are capable of individual learning, and arose through gene-based natural selection. However, the specific learned repertoires cannot be passed on to successive generations. Each organism must learn anew. For better or for worse, calculus is not programmed into the genes of any human being. Each generation must learn it from scratch. If over many generations the same learning regimen is repeated and produces some evolutionary advantage, what was once a learned behavior can to some extent become programmed into the genes. Within a single life-history of an organism, the mechanisms that produce increased knowledge can be viewed as a 'selection process.' However, in this selection process, 'brain states' take the place of genes. Behavioral units can vary from something as brief and discrete as pressing a lever to something as complex and protracted as mowing a lawn. We have yet to discover the size and shape of the brain states that are responsible for the retention of information.

A second solution to the problem posed by differences in reaction times is the 'immune system.' In order to keep up with the rapid rate of reproduction of such antigens as viruses, immune systems evolved in many larger organisms. Within the life of a single organism, selection in the immune system occurs at the cellular level. Antibodies are produced in huge numbers, each with its own reaction site. If any of these antibodies happens upon an antigen that contains a protein that matches its reaction site, this antibody proliferates and, in most cases, eliminates the antigen. Once again, the 'information' garnered through successive invasions by antigens cannot be passed on to later generations. After each invasion, a few memory cells lie in wait for any subsequent invasions. That is all. Although some workers in the early years of modern immunology thought that the process might contain some elements of Lamarckian inheritance, it does not.

Social Learning

Classic epistemology dealt with individual, isolated cognizers. How much can we learn about our environments in total isolation from all other people? How certain could Robinson Crusoe be, once marooned on his island, of any new knowledge that he obtained? After all, he had no one with whom to check his discoveries. But even the Robinson Crusoe example is not pure enough, because Crusoe brought with him language and a fund of socially acquired knowledge. What about someone who began life totally isolated from all other human beings? In the first place, such an isolated baby would rapidly die, but how about the science fiction case? How about a baby adopted by wolves or some other unlikely creature? How much could it know? How justified would its knowledge be? The answer to both questions is very little. Social organisms can learn more than solitary organisms and be more secure in this knowledge because of culture (*see* Cultural Evolution: Theory and Models).

Most discussions of evolutionary epistemology do not deal with strict gene-based biological evolution or individual learning such as operant behavior, but 'social' learning. In social learning, knowledge acquired by one organism in its lifetime can be passed on to other organisms. This knowledge is transmitted from organism to organism, not through genes, not through the passing on of any brain tissue, but through 'imitation' and 'communication.' As a result, social learning need not proceed vertically, as defined by the direction that genes take in passing from parent to offspring, but horizontally (see Cavalli-Sforza and Feldman, 1981). Education in the human species is an example of social learning. Through repeated efforts, teachers succeed in getting at least some of their pupils to be able to solve problems in calculus. Although the ability to learn in this way surely has a genetic component, social learning does not involve transmitting information genetically. As a result, it cannot count literally as Darwinian or Lamarckian. Of course, nothing keeps genes and culture from coevolving. In fact 'gene-culture coevolution' is likely to be of primary importance in human evolution (see Durham, 1991; for additional reading, see Boyd and Richerson, 1985; Cavalli-Sforza and Feldman, 1981; Eldredge and Grene, 1992; and Lumsden and Wilson, 1981).

Memetics

At this stage, advocates of evolutionary epistemology as social learning make a significant move. They cease treating bits of

knowledge, behavior, and the like as analogous to 'characters' but as analogous to 'genes.' Just as genes get passed on differentially in gene-based biological evolution, 'memes' get transmitted differentially in 'memetic' evolution (Blackmore, 1999; Dawkins, 1976; and Plotkin, 1994). Just replacing genes with memes may not sound like a very profound change, but the implications are significant. Once again, memetic evolution is not in the least Lamarckian. Literally, memetic evolution is not Lamarckian because nothing is being passed on 'genetically.' Metaphorically, it is not Lamarckian because what is being transmitted is not analogous to 'characters' but to 'genes.' It is the inheritance of acquired memes, not genes or even characters. The reason for emphasizing that memetic evolution is in no cogent sense Lamarckian, is that critics of memetic evolution think that they can dismiss this perspective simply by terming it 'Lamarckian.'

Critics of memetics provide a long list of objections to the memetic form of evolutionary epistemology. First, supposedly memetic evolution occurs so much more quickly than does gene-based biological evolution. But the same variations in speed of transmission can be found in both. Certainly viruses can spread as quickly as any meme. Second, critics complain that the analogy between genes and memes is imperfect. Genes are supposedly absolutely distinct, all of the same size and kind, and do not interact with each other. Supposedly memes exhibit none of these characteristics. Hence, the meme-gene analogy breaks down. But one need not know very much about genetics to know that genes possess none of the characteristics attributed to them by critics of memetics. Some genes are reasonably discrete; many are not, and much of the genetic material cannot be subdivided meaningfully into discrete genes. Genes vary tremendously in size, and numerous different sorts of genes exist (e.g., regulator genes). Also genes interact with each other in extremely complex ways in development. In addition, many elements of knowledge communication possess all of the preceding characteristics reasonably well developed; for example, e-mail addresses.

The chief problem with treating conceptual entities as memes is the difficulty of distinguishing *phenotypic characteristics* in this metaphorical usage. Behaviors count as characteristics in literal evolutionary epistemology. They are analogous to 'genes' in the metaphorical usage. Then what counts as phenotypic characters in the metaphorical usage? Memes get transferred from brains to air waves, to computer chips, to computer screens, to brains, etc. All of this counts as replication because information is being transmitted with relatively little loss. However, every once in a while, 'replication' is interrupted by 'translation.' Knowledge is connected causally to what it is knowledge of: you believe, for example, that barking dogs do not bite, so as you approach a barking dog, you put this belief to the test. The result will modify your belief system. The dog itself is not a meme.

As in other cases of selection, the notion of information plays a central role. One important feature of memetic replication is transmission with relatively little loss of information. One important feature of translation into the phenotype is significant loss of information. Instructions on how to make a Stradivarius violin can be transmitted from agent to agent. Antonio Stradivari might have written down these instructions, and even allowed an apprentice to watch him make a violin. If he had, this apprentice might have been able to make violins of the same caliber as did his master. He might have passed down this combination of knowledge and skill to the present. However, that is not what happened. All we have are Stradivari's violins. As repeated failures have shown, making violins based just on what we can learn from the finished product (reverse engineering) is extremely difficult, if not impossible. Future work in memetics is needed to present adequate analyses of 'information' and the 'genotype-phenotype' distinction.

A General Analysis of Selection

Early versions of evolutionary epistemology involved reasoning analogously from gene-based selection in biological evolution to knowledge acquisition. The analogical character of this activity has been the source of endless criticism. Evolutionary epistemology is 'merely' an analogy. In these arguments, the peculiarities of gene-based selection have played an inordinately important role in biological evolution. Any departure from gene-based selection in biological evolution, no matter how trivial, is viewed as a lethal disanalogy. However, an alternative view has been suggested periodically. Instead of reasoning analogously from one sort of selection process to another, present a 'general analysis of selection' that is equally applicable to all sorts of selection processes, whether gene-based selection in biological evolution, the reaction of the immune system to antigens, individual learning, social learning, memetics, etc. (Toulmin, 1972). Although the father of evolutionary epistemology, Donald Campbell (1974) was one of the strongest proponents of justifying knowledge by reference to gene-based selection in biological evolution. In his later writings he adopted this second program. Evolutionary epistemology is no longer an analogy, but it is a special case of selection. Just as the processes that result in functional organization have been isolated and analyzed as a special sort of process, selection processes warrant an equally careful treatment.

Starting with Lewontin's (1970) classic statement, successive attempts have been made to specify the essence of selection processes. According to Lewontin, the three necessary elements for selection to occur are phenotypic variation (different individuals in a population have different morphologies, physiologies, and behaviors), differential fitness (different phenotypes have different rates of survival and reproduction in different environments), and heritable fitness (there is a correlation between parents and offspring in the contributions of each to future generations). According to Hull's (1980) more general characterization, the selection process is made up of three subprocesses related in very specific ways: (1) replication of information in successive generations with only minimal modification, (2) environmental interaction that causes the preceding replication to be differential, and (3) some source of variation. The goal is to show that gene-based selection in biological evolution, the reaction of the immune system to antigens, individual learning, social learning, and other processes as well, all exhibit the basic structure of selection processes. However, such general analyses of selection do not provide any epistemological warrant. If evolutionary

epistemology is to remain 'epistemology,' then some other source of epistemological warrant must be provided (Hull, 2001).

Conclusion

Evolutionary epistemology has changed significantly from its slim beginnings. Initially, it dealt only with knowledge that is literally gene-based, e.g., a tendency to group organisms into discrete species. Evolutionary epistemology in this strict sense justified certain beliefs. However, this warrant was neither very strong nor very extensive. Evolutionary epistemology in this sense is limited only to those environmental interactions that are in the range of an organism's sense organs and that matter with respect to an organism's survival and reproduction. Evolutionary epistemology in this strict sense can provide no justification whatsoever for a belief in quantum indeterminacy.

However, the sort of evolutionary epistemology that has received the greatest attention is metaphorical in character. Knowledge is in no sense programmed into the genes to be transmitted to future generations. Instead the transmission is social. The entities being transmitted are in a broad sense memes. Numerous objections have been raised to this metaphorical evolutionary epistemology. First, so it is alleged, memes are not all that similar to genes. However, these objections stem from an unreal view of both genes and memes. The real problem is identifying something that can count as the phenotype in memetic evolution. In the absence of such a distinction, memetic evolution cannot be characterized as either Darwinian or Lamarckian. Once again, a mother dog giving her puppies fleas is not Lamarckian inheritance in either a literal or a metaphorical sense.

Whatever warrant metaphorical evolutionary epistemology provides arises from its analogical connections to literal evolutionary epistemology. Because many species of organism must be able to distinguish members of their own species to reproduce and survive, other beliefs more distantly related to reproduction and survival gain some analogical warrant. One problem with both sorts of evolutionary epistemology is that they do not distinguish between 'success' and 'truth.' Many false beliefs have been proven to be very successful with respect to survival and reproduction, e.g., the belief that God is on the side of one's own group in times of war. For this and many other reasons, a majority of professional epistemologists reject evolutionary epistemology as not being nearly good enough. Of course, professional epistemologists reach the same conclusion with respect to all other epistemological justifications as well, save their own.

A third sort of evolutionary epistemology has gained increased popularity through the years. Instead of reasoning analogically from gene-based to memebased evolution, a general analysis of selection is produced that equally applies to all sorts of selection processes from the reaction of the immune system to antigens to social learning. As promising as this research program might well be, it has one serious drawback. It supplies no epistemological warrant, at least not in any of the traditional senses. Just because a belief arose through a selection process, it does not follow that this belief is true. It all depends on the character of the selection process. For example, a belief that survives the sort of serious testing that goes on in science is likely to be true, while biblical exegesis is not likely to increase its warrant.

However, during this same period, what counts as 'epistemology' has expanded greatly. Epistemologists are no longer limited just to justifying knowledge. They are engaged in all sorts of other activities as well. For our purposes, the issue is whether or not providing a general analysis of selection can justify certain sorts of knowledge and, if not, whether it counts as 'epistemology' in any of its more recent senses.

Abstract

Evolutionary psychology adds many insights to the literature on group dynamics and small-group processes. First, groups are a fundamental aspect of human evolution, suggesting that humans have evolved a range of adaptations to deal with specific threats and opportunities afforded by living in groups. Second, an evolutionary perspective integrates knowledge from numerous behavioral science disciplines such as psychology, evolutionary biology, primatology, biological anthropology, social neuroscience, and behavioral economics that are all concerned with group dynamics. Third, an evolutionary analysis produces many novel hypotheses about different aspects of our group psychology. We show the generativity of an evolutionary psychological approach through discussing examples of research applying evolutionary thinking to understanding key adaptive group tasks such as coordination, social exchange, status, group cohesion, collective decision making, and intergroup relations.

Introduction

'Group dynamics' refers to interplays of people's social cognitions and behaviors operating within a group or between groups. The term was coined by a social psychologist, Kurt Lewin, who established the Group Dynamics Research Center in 1945 at the Massachusetts Institute of Technology. Yet, its scope has been interdisciplinary from the outset, encompassing psychology, sociology, and anthropology, among other disciplines. Recently, an increasing amount of research in this area has applied evolutionary principles to understand group dynamics (Kameda and Tindale, 2006; Van Vugt and Kameda, 2012). Applying an evolutionary perspective, group living can be seen as an adaptive strategy that increased the survival and reproductive success of ancestral humans.

One of the impetuses that promoted the shift was the social brain hypothesis (Dunbar 1993). Comparative studies with other primates and mammals have found a positive correlation between the size of the neocortex relative to the rest of the brain and the average group size of the species. Humans are ranked top, with a large neocortex and associated large average group size, which is extrapolated to be around 150 individuals from the brain data. Given the high metabolic costs of maintaining a large brain, the social brain hypothesis posits that humans have evolved large brains in order to make the most of living in large, complex social groups. In other words, many of our core cognitive and emotional faculties are likely to have been tuned to solve recurrent adaptive problems that ancestral humans have encountered in group life. The primary aim of an evolutionary approach to group dynamics is thus to identify and analyze specific adaptive group problems and the psychological architectures that have evolved to solve those problems.

Key Adaptive Problems in Group Life

Van Vugt and Kameda (2012) have proposed six key adaptive problems that ancestral humans were likely to have encountered recurrently in group life:

1. Coordinating members' activities (group coordination);
2. Exchanging resources (social exchange);
3. Negotiating group hierarchies (status);
4. Keeping groups together (group cohesion);
5. Making collective decisions (group decision making); and
6. Interacting with members of outgroups (intergroup relations).

This list is meant to be neither exhaustive nor mutually exclusive. However, it serves as a reasonable starting point for building an evolutionary framework for analyzing group processes. The list also corresponds closely to the core themes of group dynamics identified in textbooks such as Forsyth's *Group Dynamics* (2010).

Although none of these adaptive group challenges has been fully analyzed using an evolutionary framework, various research programs have contributed to developing such analyses by providing evidence for evolved psychological mechanisms that address a particular group challenge. The promise of an evolutionary group dynamics lies in the generativity and productivity of this approach in formulating novel hypotheses and providing supportive empirical evidence. This article provides an illustrative set of findings of evolutionary-inspired research programs for each of these core group challenges.

Group Coordination

How to coordinate members' cognitive and physical resources is a key to effective group performance. As a nomadic, group-living species, early humans would have had to solve problems associated with coordinating their activities with other individuals in their groups. For instance, when moving they would have had to decide where to move to and when and for how long to stay there. To solve this would have required mechanisms for identifying that situations require coordination, developing rules for how to achieve coordination (e.g., turn taking and leadership), and then carrying these rules out.

Leadership

There are multiple indications that leadership might be an adaptive solution to coordinate members' actions (Van Vugt, 2006). Whenever organisms must do things together to achieve their reproductive goals, they face a critical coordination problem, that is, how do they decide what to do when? A simple thought experiment illustrates that leadership – where one individual takes the initiative and others follow – is a powerful solution to such coordination problems. Suppose that two individuals who are thirsty must find a water hole to drink. They must stay together as a form of protection, but how do they decide on which water hole to go to? In such cases, it is adaptive for one individual to take the initiative to go to a particular hole, which leaves the other no option but to follow. Coordinating on the same water hole is the equilibrium solution to this game. An implication would be that leadership–followership interaction emerges spontaneously and does not require much cognitive computation. Unsurprisingly, then, the emergence of leadership has been documented across many different animal species that face functionally important coordination problems, including teaching in ants, choosing foraging sites in honeybees, movement in stickleback guppies, and peacekeeping in nonhuman primates (King et al., 2009).

Among humans, similar kinds of coordination problems also result, predictably, in the emergence of leader–follower relations. This occurs quickly and spontaneously across many different situations and cultures, suggesting evidence for adaptation (Brown, 1991). Of course, the exact system of leadership varies across different situations, and there is evidence for both highly democratic leadership structures and highly despotic leadership structures in humans. They likely represent different adaptive solutions to various local group conditions – for instance, dictatorial leadership might have emerged initially in response to an immediate crisis that required quick and decisive action (Van Vugt et al., 2008; Van Vugt, 2009).

Transactive Memory

Another coordination device that may have evolved to support group coordination is a transactive memory system. Wegner (1987) argued that groups can store and process more information than individuals because they can share the responsibility of knowledge storage. However, in order to retrieve the information efficiently, a shared knowledge system must exist identifying who in the group knows what – a transactive memory system. Once such a system exists, each individual member needs to store only information for which they are responsible, easing the memory load on each member but increasing the total amount of information available to the group. Division of cognitive labor is common in social insects, and one famous example is the waggle dance of the honeybee, a group decision-making device for selecting foraging sites (Seeley, 2010). Research on humans also suggests that members working in the same group often specialize in different areas, and group members are very quick at recognizing and using each other's expertise (Littlepage et al., 2008). People who are expert in a particular domain not only have more information on a given topic but also are the ones who are responsible for storing new information in their area of expertise. A set of experiments showed that teams performed better on a group task to the extent that the team members divided their cognitive tasks better. Furthermore, members of teams with better transactive memory systems also trusted each other's expertise more. There is also evidence that such systems begin to form quite quickly through normal group interaction (Moreland et al., 1996).

Structural and Social Focal Points

A game-theoretic concept discussed by Schelling (1960) – focal point – seems to play an important role in group coordination. Early work had shown that certain game solutions (e.g., equal outcomes – see Section Social Exchange) tend to receive greater support than would be expected by rational game-playing assumptions (Komorita and Chertkoff, 1973). Schelling argued that such outcome distributions 'stood out' and were salient because of their normative or focal nature. It appears that humans may have learned to use structural characteristics of their environments to help to coordinate action (e.g., meeting in the center of the village or at the water's edge). More recent research has shown that 'social focal points' are also useful in coordinated action (Abele and Stasser, 2008). Thus, normative preferences among the group members or exhibited by high-status members (leaders) can be used to guide action in ambiguous situations. Abele and Stasser (2008) showed that people were quite good at coordinating actions around social focal points, and successful coordination led to greater liking among group members. More recent research (Abele and Chartier, 2012) has shown that groups are substantially better than individuals at locating and using social focal points. Groups' superiority seems to stem from both majority processes as well as the group's ability to recognize appropriate focal points even when proposed by a single group member (see related discussions under Section Group Decision Making).

Following Group Norms

Group norms can also be helpful for coordinating behavior. Recent physiological evidence has supported the idea of evolved mechanisms to ensure greater conformity to ingroup norms (Stallen et al., 2012). Participants in their study were administered either oxytocin or a placebo and were asked to rate stimuli in terms of attractiveness. They were also shown normative ratings of each symbol by both ingroup and outgroup members. When normative ratings differed for the ingroup and outgroup, participants' ratings were more similar to the ingroup ratings but only when administered oxytocin. Thus, this hormone, which has also been related to ingroup trust and cooperation (Kemp and Guestella, 2011), also seems to help coordination by enhancing normative behavior.

Social Exchange

Social exchange – cooperation for mutual benefit – is a pervasive and cross-culturally universal feature of human group life. Exchanging vital resources with others is fundamental for any gregarious species, yet humans are unique in being able to establish large-scale cooperation with genetically unrelated individuals. Social norms related to cooperation are robust across various cultures ranging from hunter–gatherer, horticultural, tribal, and agricultural to highly industrialized societies (Henrich et al., 2004). Such norms specify how individuals should behave in a group situation where

incentives for free riding exist, including when to cooperate, how to divide group outcomes, and how to punish uncooperative group members.

Cooperation Norms

Human collective action is often governed by a norm of conditional cooperation (Fehr and Fischbacher, 2004) (*see* Human Cooperation, Evolution of). This norm dictates that an individual should cooperate if other group members cooperate, whereas he or she is allowed to not cooperate if the others defect. Fischbacher et al. (2001) examined participants' willingness to contribute in a one-shot public-goods experiment as a function of the average contribution of the other group members. Despite the economic incentives to free-ride (contribute nothing), 50% of the participants matched their contributions with the average contribution of other members. Furthermore, when participants simply observed the interaction of two players in a Prisoner's Dilemma game, they spent their own endowment to punish players who defected unilaterally but *not* players who defected bilaterally (Fehr and Fischbacher, 2004). This pattern indicates that the norm of conditional cooperation ('unilateral defection is not acceptable') is enforced by neutral observers ('third parties'). Such selective sanctioning includes not only physical punishment but also social exclusion, collectively denying the norm violator access to interpersonal relations in a group.

An evolutionary perspective suggests a novel hypothesis about the psychological mechanisms underlying enforcement of cooperation norms. Given that exchanges of valuable resources occur mainly within ingroups, violation of cooperation norms should be more serious to one's survival if committed by another ingroup member than if committed by an outgroup member. If so, then noncooperative behavior by ingroup members should be punished more severely than noncooperative behavior by outgroup members. Using the third-party punishment paradigm, Shinada et al. (2004) confirmed this prediction.

Distribution Norms

'Distribution norms' refer to a set of shared beliefs that prescribes how resources should be distributed among group members. Evidence suggests that motives for egalitarian sharing often operate strongly in resource distribution (Fehr and Schmidt, 1999; Kameda et al., 2010). For example, results from numerous one-shot Ultimatum Game experiments indicate that modal offers by a proposer for a responder's share are around 40–50% and that offers in this range are rarely rejected (Camerer, 2003). Although there are some cultural differences, extremely small offers (1–10%) are rarely seen in ultimatum-bargaining experiments conducted in a wide range of societies, including nonindustrialized as well as industrialized ones (Henrich et al., 2004). Violators of the egalitarian distribution norm are also punished. Henrich et al. (2006) conducted a third-party punishment experiment, where participants could spend their own endowments to punish an unfair proposer in the Ultimatum Game. The experimental results from 15 diverse populations showed that costly punishment by a third party was common, although the magnitude of punishment varied substantially across cultures.

Ethnographic studies show that egalitarian sharing of hunted meat constitutes a core feature of hunter–gatherer life. Compared to collected resources (e.g., cassava), hunted meat is often the target of communal sharing. Kaplan and Hill (1985) argued that the sharing system, once established, functions as a collective risk reduction device. While acquisition of collected resources is relatively stable and dependable, acquisition of meat is a highly variable, uncertain event. By including many individuals in the sharing group, the variance in meat supply decreases exponentially (Gurven, 2004; but see also Kameda et al., 2003a, 2005, for the potential free-rider problem in meat sharing). This may imply that our minds are built to be highly sensitive to cues of uncertainty in resource acquisition. Kameda et al. (2002) showed that such uncertainty cues promoted people's willingness to share with others beyond their personal distributive ideologies.

Status

Competition for status, especially among males, is a robust phenomenon across cultures. Even in modern ad hoc groups such as juries, status competition is often observed, where some jurors 'show off' their toughness for the purpose of establishing their prestige in the group while sacrificing factual discussions about the case (Hastie et al., 1983). Evolutionarily, with an increase in the size and complexity of social groups, competition for scarce resources including food, water, and sexual mates would have intensified, paving the way for the emergence of status hierarchies (Boehm, 1999; Dunbar, 2004). To climb the group hierarchy or maintain one's current status in the group, one would need to closely monitor one's relative standing in the hierarchy and to behave strategically in the group.

Signaling and Status Emotions

Along with other group-living animals, humans display various cues to signal their relative status to others. For example, nonverbal cues such as a firm handshake, a poised posture, gaze maintenance, or initiatives in conversations are among characteristics of high-status individuals when they interact with others. Some of these cues are culture specific, but other cues are easily recognizable by even outsiders who do not belong to the culture (Ridgeway et al., 1985), which may suggest their evolutionary origins.

Besides sensitivities to subtle status signals displayed during interaction, our own emotional experiences are also closely linked to changes in relative status in a group. For example, when people experience a status gain (e.g., winning an award), they tend to feel pride. Recent research has shown that, like the 'basic' emotions, pride is associated with a distinct, universally recognized, nonverbal expression, which is spontaneously displayed during pride experiences (Tracy and Robins, 2004). It has also been argued that self-esteem may be an evolved internal gauge ('sociometer') that monitors people's standing in a group and motivates actions when people feel their status is being threatened (Leary, 1999).

Competitive Altruism

When individuals can select social exchange partners freely in a group, status competition can arise for establishing a good reputation as a generous person. This phenomenon is called

'competitive altruism' (Roberts, 1998), as people compete to be chosen as exchange or coalition partners through their generosity. The anthropological literature documents various examples of excessive public displays of altruism and generosity. Experimental evidence also shows that generous individuals receive more status than nongenerous individuals and are preferred as group leaders (Hardy and Van Vugt, 2006).

Competitive altruism requires psychological mechanisms to monitor and enhance one's relative standing about generosity in a group. People are highly sensitive to social cues that suggest their reputation is under scrutiny. For example, experimental evidence shows that people behave more generously when they think they are being watched by others (Bateson et al., 2006; Haley and Fessler, 2005). Men also behave more generously to a stranger when they are watched by a potential female partner (Iredale et al., 2008).

Group Cohesion

Group cohesion has been defined as "the resultant of all forces acting on the members of a group to remain in the group" (Festinger, 1950, p. 274). In light of the importance of staying together as a unit in a hostile environment, our ancestors had to evolve mechanisms to preserve social cohesion. Furthermore, as human social networks increased in size over the course of human evolution, we would expect these bonding mechanisms to have become increasingly sophisticated. To maintain group cohesion would require specialized mechanisms to recognize oneself and others as belonging to the same group as well as mechanisms to feel emotionally connected with others in increasingly large groups.

Social Identity

Thinking of people who are not necessarily around all the time as belonging to the same group as you requires the capacity for symbolic thought whereby language or rituals become markers of shared membership. A symbolic social identity allowed our ancestors to connect with a large network of individuals who were spread around a particular area, and this may have been quite helpful in sharing resources as well as in competing with other groups. Human social identity is highly group based, and people spontaneously make us-versus-them categorizations (Tajfel and Turner, 1979). Preserving group cohesion also requires a sense of group loyalty whereby individuals are prepared to forgo attractive alternatives in favor of staying with their current group. A sense of loyalty is deeply ingrained in human psychology.

Religion, Music, and Dance

Humans have many specialized behavioral mechanisms for fostering group cohesion, which may have deep evolutionary roots. Religion, for instance, is an effective method to promote cohesion between strangers and mobilize them for joint action on behalf of a group (Atran, 2002). Similarly, dance and music may have ancient roots. According to some evolutionary anthropologists, dance and music may have evolved as adaptations for connecting large networks of genetically unrelated strangers (Dunbar, 2004).

Group Decision Making

Along with our highly sophisticated faculty for language, the ubiquity of group decision making across many societies may seem to suggest that group decisions are uniquely human. However, recent research on animal behavior suggests that this is not the case. Group decision making seems to be common in the animal kingdom as well, including in social insects (e.g., ants, termites, and honeybees), fish, and some mammals (Conradt and List, 2009; Seeley, 2010). Although 'animal group decision making' may look more like automated self-organization than deliberate coordination, the social aggregation processes (e.g., honeybees' waggle dances to recruit more fellow searchers) are in fact highly coordinated and often lead to efficient group-level outcomes. Evidently, some well-structured social coordination mechanisms that yield collective wisdom are an outcome of natural selection (Kameda et al., 2012).

Despotism versus Democracy

What is the key evolved decisional structure that enables collective wisdom in honeybees and some other animals? Conradt and Roper (2003) compared two contrasting structures, despotism and democracy, in the animal kingdom. Using a stochastic model, they showed that democratic decisions usually yield better fitness outcomes to group members than despotism – even when the despot is the most experienced group member, it pays other members to accept the despot's decision only when group size is small and the difference between their own and the despot's information is large. These findings may be extendable to human group decision making as well. Most naturally occurring environments for humans as well as other animals are characterized by large statistical uncertainties. Given that no single individual (despot) can handle these uncertainties alone even if he or she were highly experienced, the more viable and reliable decisional structure in the long run is to use groups as an aggregation device. By aggregating members' opinions, random errors in individual perceptions under uncertainty are canceled collectively, as implied by the law of large numbers in statistics (Surowiecki, 2004).

A recent study compared several decision rules, which differed in computational loads, in terms of their net efficiencies under uncertainty (Hastie and Kameda, 2005). These included the best member ('despotism') rule and the majority ('democracy') rule. Results from both computer simulations and laboratory experiments showed that the majority rule fared quite well, performing at levels comparable to much more computationally taxing rules. Furthermore, the majority rule outperformed the despotic best member rule, even when members were not forced to cooperate for group endeavor and free riding was possible (Kameda et al., 2011).

The Robust Beauty of the Majority Rule

These results indicate that, despite its computational simplicity, the majority rule can achieve surprisingly high levels of performance. Such observations may explain the popularity of the majority rule across the full spectrum of human groups from hunter–gatherer and tribal societies (Boehm, 1999) to modern industrial democracies (Kerr and Tindale, 2004), as well as the

animal cases in which democratic decisions are often more beneficial than despotism (Conradt and Roper, 2003). Of course, phylogenetically, humans are quite distantly related to honeybees and other social insects. Yet, the striking similarities in decision styles between two of the most social species on earth suggest that humans and honeybees have evolved structurally similar group aggregation mechanisms (e.g., utilizing the law of large numbers) to solve similar adaptive problems (e.g., foraging). Dealing with uncertainty is the key challenge underlying the evolution and use of these mechanisms.

Majority processes can be seen as a major instance of 'social sharedness' (Kameda and Tindale, 2006; Kameda et al., 2003b). Social sharedness is a description of the phenomena associated with shared cognitions and preferences playing an inordinate role in group decision making and problem solving. Majority rules are an instantiation of sharedness at the preference level. However, there is now a large amount of evidence that shared information, motives, and background knowledge can all play important roles in how groups reach consensus. It is often through shared cognitions and information that groups can perform even better than simple majority processes by a minority faction using such information to 'demonstrate' the correctness of their position to a majority that coalesced around a less-than-optimal choice alternative (see Laughlin, 2011; Tindale et al., 2012).

Intergroup Relations

A final problem that our ancestors faced was how to deal with members of other groups. As population densities increased in human evolution, so did the competition for scarce resources with members of rival groups. On the one hand, relations with outgroups provided opportunities for sharing resources such as food, mates, and information. On the other hand, intergroup relations could be a source of tension and conflict over scarce resources. As a consequence, humans likely possess highly specialized mechanisms that enable them to reap the benefits of intergroup relations while avoiding the costs.

Fear of Strangers

As part of this evolved intergroup psychology, humans are relatively suspicious and even fearful of strangers. Fear of strangers is an innate response that is seen among young children. Fear is strongest toward outgroup males, presumably because they constituted a considerable physical threat in ancestral times (McDonald et al., 2012). Outgroups posed not only a significant physical threat in ancestral environments but also a disease threat. A recent study showed that ethnocentrism is strongest among women who are in the early stage of pregnancy presumably because they (and their fetus) are most at risk of catching a disease (Navarrete et al., 2007).

Intergroup Aggression and Warfare

An adaptive solution to intergroup competition is engaging in organized violence against members of outgroups. Humans and chimpanzees use coalitional aggression to gain access to reproductively relevant resources such as territories and sexual mates (Brosnan et al., 2009). In both species, such coalitions usually consist of males, arguably because males have more to gain from participating in intergroup conflict – what has been dubbed the "male warrior hypothesis" (Van Vugt, 2009). Research on the male warrior hypothesis shows that men are more 'tribal' than women: they are more aggressive in intergroup encounters and have a stronger inclination to dehumanize outgroup members. Men are also more likely to make sacrifices on behalf of their group during intergroup conflict (Van Vugt et al., 2007). Consistent with the male warrior hypothesis, a recent study suggests that physically formidable men have a stronger preference for intergroup aggression and warfare than do less formidable men (Sell et al., 2009).

Recent game-theoretic simulations are consistent with the ideas of ingroup sacrifice and outgroup aggression (Choi and Bowles, 2007). These simulations showed that neither societies made up of mainly pure aggressors nor those of mainly pure altruists survived well over time. However, societies with mainly 'parochial altruists' (members who sacrifice for ingroup members but shun or aggress against outgroup members) proved to be evolutionarily stable. More recent work has begun to isolate the physiological and neurological correlates of these effects and has shown that oxytocin helps to regulate responses to both ingroup and outgroup members (De Dreu et al., 2010). Thus, behaving in ways that favor ingroup welfare appears to be adaptive for both the group and the individuals who depend on it.

The Promise of an Evolutionary Science of Group Dynamics

An evolutionary approach to group dynamics can be fruitful in at least four different ways. First, an evolutionary perspective can provide a more complete understanding of particular group processes by asking fundamental questions about the functions, origins, and evolution of these phenomena. A more complete account inevitably follows from rigorous attempts to establish conceptual links between evolutionary processes operating on ancestral populations and psychological processes operating within contemporary groups.

Second, an evolutionary perspective can help overcome biases and blind spots in the study of groups. It strikes us as odd that the social psychological literature on group decision making often focuses on what is wrong with groups, disregarding the fact that the group is the natural environment for humans. Examples include research on groupthink, brainstorming, group polarization, and information sharing. A cursory reading of this literature all too easily suggests that people are poor collective decision makers. Any such conclusion, however, is inaccurate (or, at the very least, overly simplistic), and we believe that an evolutionary perspective can produce more sophisticated and accurate conclusions about group decision making.

Third, an evolutionary approach is useful in yielding novel hypotheses about group behavior. As seen in this article, evolutionary reasoning has led to a number of new hypotheses about traditional group topics such as status, conformity, and social influence, which are unlikely to have been stimulated by other theoretical frameworks (Kenrick et al., 2003).

Finally, an evolutionary approach can expand the boundaries of scientific inquiry on group dynamics by suggesting important

group phenomena that have previously received little if any attention from group researchers. Laughter, language, gossip, dance, music, sports, culture, and religion are increasingly being understood as group-level adaptations, that is, as manifestations of psychological processes that connect individuals to each other in large and diverse groups, and these insights have benefited from evolutionarily informed inquiry.

In short, an evolutionary perspective reinforces our awareness that group dynamics are fundamental to the study of human nature. Furthermore, it provides a set of conceptual and empirical tools that can be used to understand and describe group processes more completely and accurately.

Evolutionary Medicine

Abstract

Evolutionary medicine is a set of concepts and tools with which to address medical problems. This young science asks novel questions, starting from why the human body is vulnerable to diseases to how to exploit evolutionary dynamics to improve cancer therapy. In an attempt to assess why, how, and to what extent evolutionary medicine sheds light on medical issues, this article reviews (1) the conceptual tools borrowed from evolutionary biology and their medical relevance, (2) how evolutionary medicine is evolving and its main criticisms, and (3) what practical medical applications are or can be derived.

Evolutionary medicine (EM), also known as Darwinian medicine, first emerged among the biological sciences following the motivation to understand, broadly, why the body is vulnerable to diseases (Nesse and Williams, 1996; Williams and Nesse, 1991). The value of an historical perspective for answering medical questions had first been suggested by Erasmus Darwin, a physician and the grandfather of Darwin, while the first attempt to apply evolutionary reasoning to assess medical practices dates back to the 1980s (Ewald, 1980). The field as it is currently known eventually emerged a decade later through the combined efforts of Randolph M. Nesse, a US practicing psychiatrist, and George C. Williams, a US professor emeritus of ecology and evolution, first with a major publication in the *Quarterly Review of Biology* in 1991 (Williams and Nesse, 1991) and second with a popular science book: "*Why we get sick: the New Darwinian Science of Medicine*" in 1995. Since then, the field has grown and evolutionary biologists mainly, but also some physicians, increasingly argue for the complementarity of an 'ultimate' perspective in answering medical questions (Nesse and Stearns, 2008; Nesse and Williams, 1996). It consists in understanding whether and the extent to which evolutionary processes such as natural selection and drift (e.g., hazard or chance) can account for why we are all vulnerable to diseases as well as patterns of variation in disease susceptibility among populations, individuals, and across the life span. Such an understanding enables us to question how current medical practices influence evolutionary processes (e.g., the evolution of resistance to antibiotics and chemotherapy), or might interfere with evolved predispositions (e.g., mother–infant separation at birth and the onset and maintenance of lactation). EM also has wider relevance for challenging the idea of norms in public health recommendations (e.g., nutrition), that of a perfectly designed body, or whether the pursuit of extending the life span is a sound objective when one considers how the body has been shaped by natural selection.

EM is a relatively young and fast growing area, which has, since its emergence, generated not only much promising research but also a few critiques. An undisputed benefit of applying evolutionary thinking to medical issues is in understanding the evolution of resistance to antibiotics and chemotherapy, which has obvious and critical implications for public health policies and medical practices. Given its potentially large domain of application, EM is increasingly prevalent within the biological sciences, as testified to by a number of edited books, scientific journals, workshops, and blogs. Yet, the 'e-word' has a tendency to be avoided in mainstream medicine (Antonovics et al., 2007) and the social sciences are generally suspicious of evolutionary approaches to human affairs, for several reasons. First, this avoidance is not independent of past societal experience and is likely a legacy of the infamous eugenics movement and the misuse of evolutionary theory for social purposes over the first half of the twentieth century (*see* Evolution, History of). This raises the need to define what EM is not, which has been clarified by Nesse and Williams (1996, p. 11): "We are by no means advocating that medicine should assist natural selection, nor do we suggest that biology can guide moral decisions […]. We are urging not an alternative to modern medicine but rather an additional perspective […]. We would be very much against the idea of EM as a kind of alternative cult." Second, others have questioned whether Darwin would recognize himself the premises that guide research and the extent to which adaptive hypotheses are favored over nonadaptive ones (Marks, in Elton and O'Higgins, 2008). Consequently, there is an increasing tendency to refer to evolutionary rather than Darwinian medicine, which acknowledges the fact that the discipline cannot claim any presumed recognition from Darwin himself. As for all sciences, evolutionary approaches to human affairs in general and to medicine in particular are themselves evolving. Since the launch of EM as we know it, some of the initial assumptions have been discussed, such as the validity of the EEA, i.e., the 'evolutionary environment of adaptiveness' (Foley, 1995). Ecology, a science focusing on the role of the social and biological environments in shaping disease variation, is increasingly being combined with the historical approach. Evolutionary thought now permeates research in various medical areas such as molecular biology, physiology, genetics, development, neuroscience, and psychiatry (**Table 1**). This demonstrates that EM is not a field (Stearns, 2012), but rather a series of concepts and tools to analyze medical questions from a different angle.

This article attempts to grasp why, how, and to what extent EM sheds new light on medical problems by presenting an overview of (1) the questions raised by an evolutionary perspective and their medical relevance; (2) the criticisms made of research in EM; and (3) some key fields of applications. By no means is the review exhaustive, and the reader will find more

Table 1 Evolutionary thought interacts with medical issues along a broad and diverse front

Evolutionary specialties	*Medical issues*	*Diseases*
Evolutionary genetics	Genetic basis of disease	Any with a genetic element
	Genomic conflicts	Growth disorders, cancer, mental diseases
Evolution of development	Fetal programming	Diseases of pregnancy
Evolutionary physiology	Hormonally mediated	Reproductive cancers
	Trade-offs affecting reproduction	Susceptibility to infection
	Trade-offs affecting aging	Degenerative diseases
Evolutionary neuroscience	Mental diseases	Mental disorders as disruptions of mental adaptations
	Addiction	Substance abuse
Molecular phylogenetics	Understanding origins	Cancer, emerging diseases
	Microbiomes	Forensic medicine
Evolutionary psychiatry	Mental diseases	Depression, anxiety
Evolutionary ecology	Microbiomes	Gut floras and disease
	Antibiotic resistance	Infectious diseases
	Chemotherapy resistance	Cancer

detailed information on the Evolutionary Medicine Review Web site (http://evmedreview.com) and in the burgeoning and extensive literature authored by R. Nesse, S. Stearns, L. Trevathan, G. Bentley, and P. Gluckman, to name a few.

Evolutionary Conceptual Tools and Their Medical Relevance

Mainstream Western medicine is usually regarded as taking a relatively mechanistic approach: it aims to understand how the body works and focuses on immediate (i.e., proximate) developmental, molecular, anatomical, or physiological causes of illness. It views disease as a malfunction of the body, the treatment of which generally aims to reset the body back to a 'normal' state (Nesse and Williams, 1996). An ultimate historical perspective aims to understand why we are all vulnerable to diseases in the first place. Put another way, why has natural selection left us so poorly equipped to fight pathogens and deal with new environmental conditions? As compared to the traditional proximate approach of modern medicine, an ultimate approach allows a shift in perspective to understand the flaws of bodies as the result of historical legacies or compromises between bodily functions that have been shaped by natural selection over time. An evolutionary perspective challenges the idea that the body is perfectly designed (Nesse and Stearns, 2008) as evolution is not 'an engineer' but 'a tinkerer,' with no preconceived plan, constrained to work with what is already there (Jacob, 1977). EM also emphasizes that natural selection is slow, such that the body is never entirely 'adapted' to its current environment (either pathogenic or nutritional), and maximizes individual reproduction over health (Nesse and Stearns, 2008). Given this, EM questions whether a particular bodily response to changing environmental conditions is an adaptation or a pathology (e.g., fever and child development), why the human body is equipped with apparently useless features (e.g., wisdom teeth and appendixes) and maladaptive ones, why new environmental conditions are associated with the emergence of new diseases, why we die, and whether we can win the fight against pathogens. More generally, proponents of EM consider the 'evolutionary significance' of each disease: why is it there? Why has it not been eliminated by natural selection? Why are some people susceptible to a particular type of disease while others are not? (Nesse and Williams, 1996)

The evolutionary sciences contribute both theoretical concepts and methods to address these questions. First, the evolutionary causes of diseases are generally grouped into the concepts of (1) arms races, to understand the evolution of the immune system, the evolution of pathogen and cancer resistance, as well as the expression of genomic conflicts; (2) life-history trade-offs and pleiotropic effects, reflecting the role of constraints between fitness functions across the life span and between sexes; (3) mismatch between current and past environments, which refers to the time lag human biology faces against both cultural and pathogen evolution, to understand the emergence of 'diseases of civilization'; (4) historical legacies or the idea that selection cannot start all over again and has to work with what is already there. One important method brought by evolutionary biology are phylogenetic trees (*see* Comparative Method in Evolutionary Studies), allowing us, for instance, not only to infer the genealogical relationships between clones in cancer clonal evolution (Yachida et al., 2010) but also to test hypotheses about the role of contingency (history) and constraint in the evolution of traits. Another method is population genetics (*see* Microevolution), enabling us to infer changes in allele frequency under the influence of evolutionary processes such as natural selection and drift. Most often, a combination of concepts is needed to provide a complete evolutionary account for a given disease. For the sake of simplicity, however, conceptual tools are presented here separately.

Evolutionary Arms Races: Host–Pathogen Coevolution and Genetic Conflict

Individuals compete not only with each other but also with members of other species, which leads to coevolutionary processes. To illustrate that the survival of individuals depends on their ability to constantly adapt to a changing environment, Leigh Van Valen (1973) proposed the Red Queen principle following what the Red Queen told Alice in Lewis Carroll's

piece *Through the Looking-Glass*: "now, here, you see, it takes all the running you can do, just to keep in the same place." This principle sheds light on the evolutionary processes underlying host–pathogen interactions, moving away from the idea that both parties are in symbiosis and rather to the more likely scenario that they are involved in an evolutionary arms race without end. In the battle to evolve weapons and counterweapons, humans are at a great evolutionary disadvantage. Pathogens reproduce much faster than we do; it takes thousands of years to produce 300 human generations, versus a few weeks in the case of bacteria and virus (Nesse and Williams, 1996). These much shorter generation times provide an advantage to bacteria and viruses, increasing the rate at which natural selection can favor mutations that are beneficial in the arms race. Yet, humans have evolved a myriad of defense mechanisms against pathogens, including general adaptations such as coughing, diarrhea, and vomiting as well as a sophisticated chemical weaponry expressed by the immune system deploying diverse and complex antibodies (Nesse and Williams, 1996: p. 52). In the cases of intense selective pressures, resistance to pathogens can evolve in just a few generations, and there is some evidence of selection for resistance to malaria, small pox, and tuberculosis, in the form of an increase in the frequency of an initially rarer genetic variant. However, if the outbreak is too severe and a mutation that confers counteradaptation does not already exist by chance, all infected individuals will die and the gene pool will not change. In this context, pathogens have another advantage, as the probability of a beneficial mutation already being present increases with the number of pathogens in the body, which can potentially be very high. As a result, we cannot evolve fast enough to escape from microorganisms (Nesse and Williams, 1996). Understanding processes of coevolution in host–pathogen interactions has implications across a wide range of topics, including the evolution of the immune system and defense mechanisms, the evolution of pathogen resistance and virulence, and the expression of genetic conflicts resulting from the battle between paternal and maternal genomes.

The Red Queen principle has direct implications for understanding how human interventions and practices impact on the evolution of pathogen resistance and virulence. For instance, long-term use of antibiotics, by exerting a strong selective pressure on resistant bacteria, will rapidly cause an initially rare antibiotic-resistant bacterium to increase in frequency (e.g., most strains of staphylococcal bacteria are now resistant to penicillin and ciprofloxacin). Similarly, the evolution of pathogen virulence is shaped by human practices that influence pathogen transmission: increased opportunities for transmission, decreasing the value of maintaining the host alive, are correlated with increased virulence. In the context of human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS), for instance, virulence is expected to increase in response to increased opportunities of transmission, which are dependent on the number of intravenous drug users or sexual partners. This argument is supported by demographic, historical, and epidemiological data. First, the rarity of clinical AIDS in Central Africa prior to the HIV-1 pandemic that emerged in the 1980s, combined with the long-term presence of HIV in human populations, suggest that pandemic HIV-1 had increased virulence relative to the ancestral HIV (Ewald, 1994: p. 132). Second, demographic data show that the 1980s African HIV-1 pandemic has followed a decade of extensive migration from rural to urban areas, which brought about a higher demand for sexual commerce. Conversely, campaigns advocating the use of condoms have diminished the opportunity of transmission, favoring strains with decreased virulence (Ewald, 1994). Following this line of reasoning, whenever a disease is transmitted by a vector (e.g., mosquitoes for malaria and hands of doctors for puerperal fever) thereby increasing the opportunities for transmission as compared to personal contacts, virulent pathogens immobilizing the host will become more frequent (Ewald, 1994). The evolution of virulence as a response to practices can occur quickly because reproductive cycles are short in pathogens, and this can be exploited to decrease the incidence of virulent strains.

The arms race metaphor is also useful in questioning whether or not we should treat symptoms. In other words, is the bodily response to an infection such as coughing or diarrhea a manipulation of the pathogen to increase its probability of transmission (e.g., rabies) and/or an adaptive immune response to eliminate the pathogen (e.g., fever)? In many cases, the defense and the manipulation hypotheses are not mutually exclusive. For instance, diarrhea following infection by *Shigella* helps both the bacteria to spread and the host to resist the infection, with the administering of some treatment (diphenyloxalate) delaying the recovery (Ewald, 1994). Then, if a defense is adaptive, should we block it? It is important to note that the onset of defensive mechanisms is not without cost (for instance, high fever is related to increased probability of tissue damage) and if alternative treatment such as antibiotics and antipyretics could eliminate the infection without incurring the defense cost, then treating the symptom should be preferred (Ewald, 1980). However, if the pathogens become resistant to antibiotics and very high dosages are required, the decision should be reevaluated depending on the goal of the treatment (eliminating the disease or managing pain) (Ewald, 1980). In general, the symptomatic treatment of disease is more relevant with manipulative manifestations rather than defensive manifestations of the disease (Ewald, 1980). The EM approach can thus either recommend treatment or its abstention, which depends on testing the validity of the manipulation and defenses hypotheses.

Finally, the arms race concept is important for understanding diseases that result from a deregulation of the evolutionary conflict between the sexes, such as preeclampsia, Angelman syndrome (AS) (neurogenetic disorder associated with various symptoms including intellectual and developmental impairment), or Prader–Willi syndrome (PWS) (neurogenetic disease associated with a wide range of symptoms including excessive eating and morbid obesity). An arms race between the sexes may occur when maternal and paternal genes do not share the same interest over the amount of resources invested in each offspring (i.e., when maternal investment of resources in one offspring reduces the amount of remaining resources available for other offspring who do not share the same father), and when there is the opportunity to manipulate parental resources (i.e., when there is physical contact with the maternal parent such as in angiosperms and in mammals)

(Úbeda and Wilkins, 2008). The arms race results in the differential expression of the copies of a gene depending on their parental origin, with one parental copy being overexpressed and the other underexpressed, a phenomenon called genomic imprinting (Haig, 2002) (*see* Sociobiology: Overview). One of the best known examples of genomic imprinting modulating access to maternal resources in mammals is the gene coding for the insulin-like growth factor 2, mainly responsible for embryonic growth, where the paternal copy is overexpressed and the maternal copy underexpressed or silent. Most known imprinted genes are involved in growth, but there is also some evidence that they are involved in neural development, with paternally imprinted genes being associated with the hypothalamus (development of emotions) and maternally inherited genes being associated with the cortex (development of intelligence). A deleterious recessive mutation on an imprinted gene is likely to be associated with a strong phenotypic effect, as the copy from the other parent cannot maintain the normal phenotype. For instance, when there is a modification of an inherited allele on chromosome 15, individuals develop either AS if the modification is on the maternal copy or PWS if it is on the paternal copy. In AS, the loss of the maternal allele selected to reduce the demand for maternal resources is associated with increased activity and prolonged suckling of the new born. In addition, individuals with AS suffer mental retardation and difficulties with speech. Conversely, in PWS, the loss of the paternal allele selected to increase the demand of maternal resources leads to reduced activity and poor suckling, hyperphagia during childhood, obesity, and poor libido (Bentley & Aunger, in Elton and O'Higgins, 2008). Regarding mechanisms, an imprinted gene expression is associated with epigenetic modification on each allele, such as DNA methylation and histone modification (*see* Epigenetic Inheritance). These modifications are established during gametogenesis but can be reprogrammed later in life, and a failure of this system could lead to the development of diseases at any stage of life. Dietary conditions at critical development stages may result in a shortage or an excess of methyl donors, which might alter the pattern of expression of imprinted genes. Given the current state of knowledge, however, it is unclear whether and when such alteration is adaptive or pathological, and it has been suggested that simply supplying the missing nutrient at a later developmental stage may create a new set of disease conditions (Úbeda and Wilkins, 2008).

Evolutionary Constraints: Life-History Trade-Offs and Aging

An evolutionary approach views the body as resulting from a series of trade-offs between fitness functions: when resources are limited, resources are traded off between competing functions such as growth, survival, and reproduction. Allocating more resources to reproduction implies a smaller allocation to growth such that, for instance, across species and within species, those with an earlier age of first reproduction also tend to have the shortest growth (Stearns, 1992). It follows that there is no such thing as a Darwinian Demon (a hypothetical organism that can maximize all elements of its fitness simultaneously), as not all functions can be simultaneously optimized. Trade-offs vary within life cycles as defined by patterns of growth (infancy, juvenility, childhood, adolescence, and mature adult), and within any specific life cycle, natural selection is expected to have shaped the optimal allocation of resources between different functions depending on individual characteristics (e.g., sex) and environmental circumstances (e.g., availability of nutritional resources). At a proximate level, such trade-offs are mediated by hormones (steroids and metabolic), which vary in their expression between individuals and across the life span; for instance, testosterone is not only associated with enhanced competitive abilities and mating success but is also an immunosuppressant. The conceptual foundation that views organisms as having life cycles rather than having a life cycle (Bonner cited in Stearns, 1992) and that within each life cycle, phenotypic traits result from the action of natural selection on trade-offs between fitness functions has several theoretical and practical implications.

First, it is directly related to the antagonistic pleiotropy hypothesis for understanding the evolution of senescence (Williams, 1957), one of the most puzzling questions in evolutionary biology. Building on the work of Haldane (1941), who reasoned that diseases that are expressed late in life after reproduction might have already occurred (e.g., Huntington disease) cannot be eliminated by natural selection, and Medawar (1952), who pointed out that selection weakens with age as fewer individuals are still alive within older age groups, Williams proposed that genes causing death can be selected for if they provide a fitness advantage early in life (Williams, 1957). This hypothesis, which assumes that senescence is a life-history trait shaped by natural selection, is prevalent in the literature and is supported by studies showing (1) that there is heritable variation for senescence and (2) alleles that slow aging also often reduce reproduction (reviewed in Partridge and Gems, 2006). There is still controversy in the field as not all genes that cause senescence necessarily have a benefit, but EM has changed the way researchers view the aging process by stimulating the investigation of biological variation in aging rates among animal species and individuals (Partridge and Gems, 2006). Along these lines, studies of centenarians have revealed that heritable variation in inflammatory activity could be involved in shaping senescence rates. Senescence is now increasingly considered to be a by-product of selection for the inflammatory response, with the benefit of counteracting agents early in life being downsized by continuous and long-term proinflammatory condition later on, in a life stage largely unforeseen by evolution (Franceschi et al., 2000).

Second, a life-history perspective questions the idea of norms in child developmental medicine. Because of the diversity and unpredictability of environments, natural selection is expected to have favored the ability to adjust development to local socioecological conditions, a phenomenon known as developmental plasticity (*see* Evolutionary Developmental Psychology). For instance, across populations, the pace of development is correlated with subadult mortality in the local environment, controlling for energetic availability (i.e., the velocity of growth controlling for body size), the development being faster in high-mortality environments. It suggests that there has been selective pressure for accelerating life history when risk of mortality, and thus the risk of not reproducing, is high (Walker et al., 2006). In addition, growth

trajectories and the onset of puberty depend on the availability of resources, influencing the strength of trade-offs. Environmental effects such as low weight gain during childhood due to malnutrition or resulting from intense sport activity is correlated with delayed age at sexual maturation (see Gluckman and Hanson, 2006). Overall, those with the earliest age at menarche are those who were born in a high-mortality environment and encountered good conditions during childhood. This adjustment explains why girls born in developing countries and adopted at an early age in a developed country have a precocious development (Gluckman and Hanson, 2006). An evolutionary approach views early age of menarche as an evolved response to local environmental conditions rather than a pathology, which in turn questions the rationale for prescribing gonadotropin suppressors to retard sexual development. More generally, the idea of a norm for child development is challenged.

Environmental Mismatch and Genetic Quirks

The rationale underlying the mismatch hypothesis is that environmental change creates a new set of conditions that the genome has not experienced before. Some heritable variation will become helpful, harmful, or neutral depending on the environment. It follows that diseases are not caused by defective genes but by novel environments (Nesse and Williams, 1996). The mismatch may result from rapid and recent cultural change in diet and change in life history and it has been argued to account for the 'diseases of civilization' such as obesity, allergies, vitamin D deficiencies, or addiction (Nesse and Williams, 1996). For instance, a low availability of fat and sugar during human evolution has selected for an intense craving for those nutrients. Unfortunately, the exploitation of this innate taste by the food industry has contributed to increase the prevalence of obesity and diabetes in the recent past, where fat and sugar have been made available in large quantities. Similarly, a change in women's life history, i.e., earlier age at menarche, later age at first birth, and lower number of children, exposes women to different hormonal patterns, which is not independent of the occurrence of reproductive cancers (Eaton et al., 1994). Provided that the new environmental conditions are stable enough over generations, genetic evolution might eventually catch up with cultural change. For example, the reliance on dairy products for subsistence has selected for the ability to digest lactose during adulthood among populations who have practiced agriculture. However, at any point in time, there might be a mismatch between the current environmental conditions and those that have shaped the evolution of a particular trait.

One highly cited example of a genetic quirk (genes that have no deleterious effects except when exposed to novel environments (Nesse and Williams, 1996: p. 106)) is myopia, the development of which requires both genetic and environmental factors. Twin studies have revealed that myopia has a strong genetic basis, and the disease is expressed in about 25% of Americans (Nesse and Williams, 1996). This high frequency is puzzling, as surely this condition should have been selected against before the advent of modern vision correction devices. A longitudinal study shows the role of environmental novelty in the onset of the condition. Among the East Greenland Inuit, no cases of nearsightedness were reported in the 1950s, but by 1994, myopia had increased by 25 and 17% among the 5- to 9-year-olds and the 10- to 14-year-olds, respectively (Norn, 1997). Although the myopinizing factor is unknown, it has been suggested to be either schooling and/or change in diet as such cultural pressures were not present before 1942. The value of the mismatch hypothesis lies in both challenging the idea of an optimum body and highlighting the importance of cultural change for the onset of diseases. As Konner put it (cited in Nesse and Williams, 1996: p. 106) "the discovery of a genetic determination for a disorder may provide the best hope for an environmental treatment of it."

Historical Legacies and 'Scars' of Evolution

The features of human biology have been established by long-term historical processes, which combined with the impossibility for natural selection to start all over again, lead to the occurrence of some design flaws. For instance, we share with all vertebrates an air–food traffic problem in that food might go down 'the wrong pipe.' This results from the position of the esophagus, located behind the trachea, which must be closed by an epiglottis when food travels to the stomach. This anatomical flaw, leading to 1 in 100 000 people choking to death each year, is a legacy from a remote ancestor, a minute wormlike animal for whom the digestive system was co-opted to serve a respiratory function (Nesse and Williams, 1996). Historical processes have also been invoked to explain why 70–80% of US citizens are affected by back problems each year, why we have varicose veins and hemorrhoids, and why our cooling system is not good enough to protect us from sun stroke (for a detailed account of the 'scars of evolution,' see Morgan, 1994).

Of particular interest are the 'scars' associated with shifting from quadrupedal walking to bipedal locomotion during human evolution. Although some adaptive changes have occurred, some flaws still persist with regard to the skeleton and the regulation of blood pressure. First, the verticality associated with walking on two rather than four legs imposed new constraints on the originally single-arched spine. The human backbone now develops into an S shape during infancy, which partly deals with the new vertical weight-bearing stresses. At 4 months, an upward curve along the neck region allows babies to maintain their head up, and by 1 year, an additional backward curve down the lower trunk allows babies to walk. To be able to pivot on the front end, the backbone S shape has been accompanied by a change in the shape of vertebrae into that of a wedge (Morgan, 1994). This in turn weakens the backbone later in life in the region where the wedge shape is most pronounced, i.e., the lower back. Second, verticality imposes new gravitational constraints on circulation, as blood returning to the heart must overcome a higher gravitational pull than it did on four legs. This leads to varicose veins despite a system of valves in the legs to prevent blood reflux, and hemorrhoids, which does not even benefit from a valve system as the anus is not lower than the heart in a four-legged mammal (Morgan, 1994). Overall, historical legacies have been implicated in the etiology of acne, anorexia,

anxiety, back pain, cancer, obesity, sleep disorders, snoring, and sun stroke thrombosis (Morgan, 1994).

Criticisms

If the e-word has been avoided in medical publications when referring to evolutionary processes, the science of EM, as advocated by Nesse and Williams, has received little direct criticism so far (but see Marks in Elton and O'Higgins, 2008; Cournoyea, 2013). This situation likely results from the appeal of EM in providing a theoretical framework in which researchers, students, and patients can organize medical facts, combined with the more general acceptance and fashion of evolutionary theory in explaining the living world among scientists, journalists, and the general public alike. Yet EM is a science, and as such, requires a critical perspective. Concerns can be specific to the use of evolutionary theory in medicine (Marks, in Elton and O'Higgins, 2008) and can also be more general and echo those directed at evolutionary biology (e.g., 'the adaptationist program' Gould and Lewontin, 1979), biological anthropology and medical ecology (e.g., too little interest in the role of political economy in shaping human/environment coevolution: Singer, 1996). More generally, EM is questioned regarding (1) its assumptions about "biology, morality, and society" (Marks, in Elton and O'Higgins, 2008) and (2) its relevance to practical medicine (Cournoyea, 2013).

The first area of concern with EM is that as a science, it is not independent from the political and economic contexts in which it is practiced, which has implications for the emergence and shaping of scientific ideas as well as their applications (Marks, in Elton and O'Higgins, 2008). The use of evolutionary theory in medical matters has known several forms or meanings, from the British and American Eugenics societies of the 1920s aiming at improving the human race, to modern EM aimed at understanding the vulnerability to diseases. Yet Marks argues that it is not possible to distinguish between the use and misuse of evolution in medicine as it is always related to the political system in which it is expressed (Marks, in Elton and O'Higgins, 2008). For instance, following the idea that different populations have known different evolutionary histories, as exemplified by the phenotypic variation in the ability to digest milk, there has been an appeal for tailoring medicine to different ethnic populations. The economic potential of such a field has not escaped lobbyists, who soon developed the field of pharmacogenomics aimed at improving the efficacy of treatment by tailoring drugs to individual genetic makeup. This is exemplified by the first 'ethnic' drug, BIDIL, a therapy to treat heart failure among African Americans (a group known to suffer higher rates of heart diseases), which was approved by the US Food and Drug Administration in 2005. The rationale for the drug, however, ignores current knowledge on the sociocultural causes for health disparities among groups as well as genetic variation within groups. It turned out that BIDIL was medically inefficient, its mechanism was not really understood, and it became a financial flop. This example echoes some criticisms that have been put by 'critical medical anthropologists' to medical ecologists and biological anthropologists, pointing out that denying the political dimensions of science is itself a political act, which can be dangerous in an era where health is a public responsibility funded by tax payers (Morgan, 1993).

A second set of concerns touches on the premises on which research is built and how it might shape the interpretation of the causes of diseases. This criticism is more about the evolutionary sciences as a whole than about EM, and dates back to 1979. In the 'Spandrels of San Marco,' the biologists Gould and Lewontin famously cautioned against the 'adaptationist program,' which consists, among other things, in seeing all parts of all living things as having evolved by natural selection to fulfill a specific function (Gould and Lewontin, 1979). They argue in favor of a pluralistic approach in which adaptation is not viewed as the default explanation, calling for a consideration of the role of other evolutionary processes such as drift (when a change in allele frequency is due to stochastic events rather than selective processes) (*see* Microevolution). For instance, as history and chance can play a large part in the evolution of a trait (Jacob, 1977), data on the demographic history of a population (e.g., past population bottlenecks) and its genealogy (e.g., founder effects) are needed to tease apart whether a disease is present due to selective processes (e.g., sickle-cell anemia selected for its protective effects against malaria) or demographic history (e.g., Sachs disease among Ashkenazi Jews due to a founder effect). Focusing only on adaptive patterns is problematic when patterns of variation result from both selection and demographic effects. Thus, Marks wonders whether 'Darwin would recognize himself' in modern EM, as Darwin's own writings favored a pluralistic approach, and reminds us that since Darwin offers scientific legitimacy, this legitimacy can be exploited (Marks, in Elton and O'Higgins, 2008).

Third, resistance might have been fostered by the strong revelatory promises and deterministic feel associated with the human genome project, in which the role of current socio-ecological forces in shaping phenotypic variation are secondary. More generally, one area of contention is the greater importance given to phylogenetic (proximity of descent) as opposed to adaptive (shaped by the environment) divergence, or the role of ancestry versus ecology. While the genetic difference between humans and chimpanzees is very small, we are different in many respects. Are chimpanzees the most relevant models to understand humans (due to low genetic divergence)? If one wants to understand cooperative breeding and its implications for mother–infant bonding, or the relationship between testosterone, survival, and paternity, one might better turn toward the *Callitrichids*, more distant genetically but showing convergent evolution for those traits. The problem of disconnecting genetics from ecology extends to other areas of research, and in particular to what is now known as the Paleodiet. Since its first formulation, the Paleodiet has gained considerable credit in popular science, the media, and the public, and countless books advocating the Stone Age diet have flourished. Mainly based on studies of modern hunter-gatherers, the idea is that humans are adapted to Palaeolithic times, and therefore anything related to agriculture

and the modern environment is detrimental. In particular, it recommends a special ratio of plant and protein (although the ratio itself has varied depending on the way the data are analyzed). While an historical perspective is highly relevant to understand why there is little chance that many of us are adapted to a large quantity of glucose–fructose syrup, this perspective tends to ignore the tremendous climatic variation during the Pleistocene (200 000 years), the high ecological variation in the diet of modern hunter-gatherers (Elton and O'Higgins, 2008), and the fact that modern hunter-gatherers probably descend from a selected sample of historical populations who did not take up agriculture. The idea of a threshold is also 'antievolutionary' (coined by Marks in Elton and O'Higgins, 2008), as many instances of genetic adaptations have been documented since the advent of agriculture (e.g., lactase dehydrogenase). This exemplifies how nice stories can take over the public space even though they might not stand up to data.

Finally, the utility of the approach of EM in the everyday practice of the doctor has been questioned (Cournoyea, 2013), as medicine and evolutionary biology have different goals (e.g., treating patients versus understanding why diseases materialize in the first place). Some regret the lack of definitive answers and clear guidelines (Marks, in Elton and O'Higgins, 2008). This echoes the more general concern about the value of fundamental as opposed to applied research. Applied research cannot be designed before fundamental questions have been solved, however. For instance, understanding the phenomenon of infection transmission in the case of puerperal fever has led, although with some delay, to better hygiene in hospitals wards and ultimately, better health. As for the lack of definitive answers, one might contend that a major input of EM is to caution against clear normative guidelines without an understanding of the underlying processes. At this stage, EM is better viewed as a tool to assess current medical practices and public health initiatives. Illustrative examples of potential applications devised by an evolutionary perspective are detailed in the next section.

Applications

The science of EM has been about 20 years old at the time of writing this article. Attempts to draw concrete applications from EM, however, have taken off only recently. In 2008, an edited book by Elton and O'Higgins "*Medicine and Evolution: Current Applications, Future Prospects*" provided one the first attempts to face the challenge posed by translating theory into practice, discussing to what extent it is possible and what areas appear the most promising. In this line, peer-reviewed journals such as *Evolutionary Applications* and *Evolution, Medicine and Public Health* have recently been launched by the Evolution, Medicine, and Public Health Foundation. Overall, the young science of EM has tremendous potential to understand the etiology of diseases, assess current practices, and contribute to future diagnostic and therapeutic tools as well as public health programs. Such applications remain marginal to mainstream medicine, however, which is not independent from the fact that EM is not included in the curricula of medical schools, yet. Proponents of EM argue that rather than adding to the existing burden of students, including EM would provide medical students with a framework within which to organize facts (Nesse and Stearns, 2008). This aspect is not covered here; for more details on the place of EM in medical school, see Nesse and Schiffman (2003).

Antibiotic Management in Hospitals

Bacteria can evolve resistance to antibiotics very rapidly. After the initial therapeutic revolution brought about by antibacterial antibiotics, their intensive utilization and misuse led to a sharp increase in the frequency of resistant bacteria. We are now in the 'postantibiotic era,' in which the long time needed to develop new antibiotics may leave us short of therapeutic options. Bacteria resistance is particularly lethal in intensive care units, where the number of hospital-acquired (nosocomial) infections can be counted in the millions and the number of deaths in the thousands, not to mention the cost of prolonged stay in hospital. Here, an evolutionary approach can help understand and prevent the development of single- and multidrug resistance as well as investigate the reversibility of resistance. Using this approach to control the evolution of resistance generally involves the alteration of the environment to maintain the prevalence of sensitive strains. It relies on the effect of pleiotropy, when the expression of resistance to an antibiotic is also associated with a reproductive cost (for the bacteria) in the absence of the antibiotic, and fluctuating selection, where genetic variation is maintained (the presence of both sensitive and resistant strains) by rapidly changing the selective pressures, i.e., the antibiotic environments. As resistance to an antibiotic is most often associated with a cost in the absence of the antibiotic, removing the selective pressure allows sensitive strains to outcompete and displace resistant strains.

To reduce the rate of evolution of multidrug resistant bacteria, the first initiative has been to limit the total amount of antibiotic used in hospitals; however, medical, social, and economic forces have prevented the full use of this opportunity. Consequently, strategies making use of fluctuating selection, i.e., increasing the heterogeneity of antibiotics to limit the potential for natural selection to favor resistant strains, have been proposed. These are mainly antibiotic cycling, where the antibiotic is periodically replaced but all individuals within a ward are exposed to the same antibiotic at a given time, and antibiotic mixing, where the antibiotic is periodically replaced but where all individuals within a ward are exposed to different antibiotics at a given time (see **Figure 1** for an illustration). Empirical evidence for the efficiency of cycling strategies is controversial and most models have rejected it in favor of mixing strategies (Bergstrom et al., 2004) as the rate at which bacteria encounter new antibiotics is faster (i.e., increases heterogeneity), thereby reducing the amount of time during which resistance can rise to a high frequency (**Figure 1**). Mixing strategies, however, present the disadvantage of allowing horizontal gene transfer between bacteria that are resistant to different antibiotics and might therefore facilitate multiple drug resistance. Consequently, cycling strategies have seen a resurge of interest, with theoretical work showing that multiple resistance is less likely to occur if the antibiotic associated with the higher

Figure 1 Effects of cycling and mixing on the selective conditions faced by a bacterial clone. Cycling offers greater heterogeneity at the level of the ward, but mixing offers greater heterogeneity at the level of the individual patient. Taken from Bergstrom, C.T., Lo, M., Lipsitch, M., 2004. Ecological theory suggests that antimicrobial cycling will not reduce antimicrobial resistance in hospitals. Proceedings of the National Academy of Sciences of the United States of America 101(36), 13285–13290. http://dx.doi.org/10.1073/pnas.0402298101.

resistance cost is used first, as the higher the cost the quicker the decrease in the frequency of resistant bacteria when the second antibiotic is used (Goulart et al., 2013).

The displacement of resistance remains challenging. It can take years due to phenomena such as compensatory evolution (the cost has been removed) and coselection (mutation conferring resistance is maintained through the selection of another portion of DNA to which it is linked), and it may not be practical given the time window available to the patient (Andersson and Hughes, 2010). In addition, the cost of resistance to an antibiotic varies among strains and from location to location, and therefore phylogeography of the pathogen would be required in designing strategies. Finally, the quantitative predictions of the models are dependent on the assumptions regarding the type of antibiotics used as well as their similarities. Overall, the very complex ecology of bacteria and their great ability to develop resistance, combined with the difficulty for models to make realistic predictions and the relatively small scope for experimentation in hospitals, together imply that we are not there yet, but evolutionary reasoning appears to be central if we are to make any step forward.

Cancer Therapy

Cancer was first described as an evolutionary process by Nowell in 1976. Most cancers are ecosystems of evolving clones (a clone is a group of cells related to each other by descent from unitary origin) that are escaping replication controls and DNA repair systems. The evolution of cancer cells is characterized by a sequence of clonal expansion, genetic diversification, and clonal selection. Most cancers are monoclonal in origin, but the expansion of population size and constant acquisition of new mutations lead to an increased genetic and phenotypic heterogeneity within a tumor (subclones). That not all mutations occur in the same cells explains partial tumor response to therapy and the emergence of drug-resistant cells. In this context, chemotherapy favors the development of metastatic cancers in two ways. First, it favors chromosomal instability thereby increasing the frequency of mutations, some of which potentially lead to resistance. Second, chemotherapy acts as a selective pressure against sensitive clones (decreasing their frequency) and for resistant ones (increasing their frequency). In other words, most single-target therapy will lead to the selective survival of a drug-resistant clone, which will expand and become dominant.

The opportunities for EM to contribute to cancer therapy reside in the exploitation of the evolutionary dynamics of cancers. While the oncologist can predict the future (which new selective pressure will be used), the cancer cannot: natural selection does not favor resistance for a chemotherapy that has never been experienced. Several potential avenues have been proposed (reviewed in Gerlinger and Swanton, 2010). First, assessing changes in clonal composition over time can tell us about which clone is resistant and which clone is sensitive to intervention. Most current-generation diagnostic genomic tests for cancer only inform about the presence/absence of cancer but do not inform about the proportion of each clone. This limits our ability to readjust therapy before progression occurs, or to track clonal bottlenecks (i.e., a decrease in clonal heterogeneity and thus in the potential to evolve) during the course of treatment by specifically targeting resistant clones. While assessing change in clonal composition is technically feasible through the advent of next-generation sequencing and new noninvasive techniques measuring heterogeneity in circulating tumor DNA in the plasma, the time and cost involved with this approach render it still not practical at the public health scale. Second, theoretical models and *in vivo* experiments propose a move away from a 'treatment for cure' strategy (generally a high-dose treatment aiming at killing as many cancer cells as possible) to a 'treatment for stability' strategy, a treatment that aims to prevent the elimination of sensitive clones. According to models and *in vivo* experiments, this latter approach would provide patients with a better life

Figure 2 Adaptive versus standard therapies for mean tumor burden. To test the results of the models, experimental testing was conducted with mice inoculated with ovarian cancer cells. The two panels represent two different experiments. Each experiment included four animals in three experimental arms: (a) control (vehicle only); (b) 'standard' high-dose therapy consisting of 60 mg kg^{-1} each 4 days for three doses; (c) adaptive therapy that begins with a dose of 50 mg kg^{-1} and then adjusts the dose to maintain a stable tumor volume. The arrows on the x-axis represent days in which therapy was given in the adaptive group. The *y*-axis is the mean tumor volume for the four animals in each experimental group, and the *x*-axis is the time from inoculation of 10^7 tumor cells. Adaptive therapy can maintain small tumor and animals can survive indefinitely; Standard therapy is followed by substantial effect but it is followed by the recurrence of the tumor and the death of the animals. Adapted from Gatenby, R.A., Silva, A.S., Gillies, R.J., Frieden, B.R., 2009. Adaptive therapy. Cancer Research 69(11), 4894–4903.

expectancy as compared to high-dose chemotherapy (**Figure 2**; Gatenby et al., 2009). Third, the use of evolutionary tools such as phylogenies offer promising avenues for the early diagnosis of slowly evolving cancer at a stage where it is still, potentially, curable (Yachida et al., 2010). For instance, in the case of pancreatic cancer, a quantitative analysis of its genetic evolution shows that at least 10 years elapse between the initiating mutation and the birth of the nonmetastatic founder cell, and five more years are required to reach the metastatic state, after which patients are being diagnosed but the cancer is no longer curable (Yachida et al., 2010). These tools combined with advanced imaging and blood tests can offer an opportunity for early detection. Finally, it has also been suggested that drugs that promote genetic instability would be lethal for cancer (Gerlinger and Swanton, 2010). While phenotypic heterogeneity within clones is the necessary condition for the evolution of resistance, too much instability has costs for cancer in that it would produce too many deleterious mutations. More generally, all this research suggests that we must move away from the prevailing

monoclonal model and aggressive chemotherapy to develop strategies that take advantage of clonal heterogeneity (Gerlinger and Swanton, 2010).

Helminths (Parasitic Worms) and Crohn's Disease

Diseases resulting from an acute and mistaken response of the immune system such as allergies, Crohn's disease, and inflammatory bowel diseases are common in industrialized countries but rare in the developing regions of the world. According to the hygiene or 'old friends' hypothesis, these new diseases result from a mismatch between the environment in which the immune system has evolved and the modern urban environment where, following improvements in hygiene practices, helminthic infestation has dramatically reduced (Rook, 2012). However, the immune system has coevolved with parasitic worms so that the presence of helminths actually decreases the immune response. Because helminthic infestation offers protection from immunological diseases, poor helminthic infestation is believed to be the missing immunoregulatory factor that has led to a recent increase in autoimmune diseases (Rook, 2012).

There have been a number of studies looking at the role of helminthic therapy for a number of conditions including asthma, allergy, cancer, celiac disease, diabetes, and inflammation. Perhaps the most striking study to date is one that investigated the response of patients affected by Crohn's disease to helminthic therapy. The study, involving 29 patients, found that remission was increased by 72% after 24 weeks of treatment consisting of ingesting ova of *Trichuris suis*, an intestinal parasitic worm (**Figure 3**; Summers et al., 2005). Similar effects have been found for colitis, and no secondary effects of helminthic therapy have been observed to date. Since then, other worms have been identified, especially hookworm, which, if associated with anemia in poor regions, alleviate the symptoms of Crohn's disease in rich regions. Some have cautioned against the view that helminth (non)infection is the cause of all inflammatory diseases, particularly those in infants and those that present multiethnic prevalence (Reddy and Fried, 2009) as well as against the risk of multi-infections or coinfections. Yet, while more research on a larger scale is warranted to replicate those results, helminthic therapy offers exciting new avenues to treat inflammatory diseases.

Emergency Medicine and Intensive Care

It has been proposed that multiorgan failure observed in critically ill patients is, rather than a failure per se, a protective mechanism that would enhance the chances of survival of cells and organs in the face of an 'overwhelming insult' (Singer et al., 2004). Failure was previously envisaged as an abnormality resulting from an inflammatory response during an initial phase and followed by tissue hypoxia, cell damage, and organ dysfunction in a later phase. However, several observations challenge this view, among which are the facts that multiorgan failure is not associated with an increased necrosis of organs and that intervention on the critically ill such as blood transfusion and ventilation have been associated with adverse outcomes. It is increasingly being recognized that rather than hypoxia per se, the phenomenon corresponds to a reduced use of oxygen by cells which enter a dormant state in the face of reduced oxygen delivery to enhance the prospect of cell survival. A few studies suggest that interventions aiming at increasing/restoring the amount of oxygen in critically ill patients through ventilation or blood transfusion might actually be more damaging than restorative (see for review Bentley & Aunger, in Elton and O'Higgins, 2008). Viewing multiorgan failure as an adaptation rather than an abnormality might have important implications, as interventions might be harmful if they interfere with a response that is primarily protective. While a promising path, more studies directly assessing the adverse impact of routine interventions in palliative care are needed.

Birth and Parenting

Since EM has been launched (Nesse and Williams, 1996) as a complementary approach to mainstream medicine, one

Figure 3 Crohn's disease and helminthic therapy. (a) Percentage of patients achieving remission or response at week 12 or 24 after initiating ova therapy. (b) Mean change in Crohn's disease activity index (CDAI, mean (SD)) for respondents to ova therapy. CDAI <150 is remission. $p < .0001$, week 12 or week 24 compared with baseline (time 0). Taken from Summers, R.W., Elliott, D.E., Urban, J.F., Thompson, R., Weinstock, J.V., 2005. Trichuris suis therapy in Crohn's disease. Gut 54(1), 87–90.

core interest has been to question practices in pregnancy, childbirth, and mother–infant relationships. First, EM questions the general practice of supplementing pregnant women with iron. Iron deficiency during pregnancy is thought to have evolved in response to pathogenic pressure (Nesse and Williams, 1996). Indeed, nearly all bacteria, fungi, and protozoa depend on a continuous supply of host iron for their growth and hosts have evolved a variety of defense mechanisms to preclude pathogens from acquiring essential material (Weinberg, 2009). It has thus been argued that low iron levels may protect against acute infection in young children (Nesse and Williams, 1996). Similar mechanisms exist in other species and, for instance, the iron-binding protein ovotransferrin in an egg white protects the yolk from most infections (Weinberg, 2009). If iron supplementation has potentially little effect in developed countries where parasitic load is low, such intervention might be more problematic in developing countries. Second, evolutionary studies have questioned the rationale underlying the treatment of jaundice in the preterm infant (Hammerman et al., 1998). It has been suggested that serum bilirubin, rather than being a toxic metabolic waste, is a protective antioxidant defense mechanism. This is especially relevant for preterm neonates for whom the concentration of antioxidant enzymes is reduced. Supporting this argument, a study involving 41 premature neonates revealed a relatively high correlation between serum bilirubin in premature and antioxidant potential during the first week of life (Hammerman et al., 1998; **Figure 4**). Third, EM has questioned mother–infant sleeping patterns at hospitals and the extent to which early sleeping arrangements influence long-term breast-feeding practices (Ball in Elton and O'Higgins, 2008). Evidence from comparative analyses suggests that the development of an early close physical relationship is critical for infant survival and normal development (Ball in Elton and O'Higgins, 2008). In particular, the onset, efficiency, and duration of breast-feeding are not independent from skin-to-skin contact in the immediate postnatal period. For instance, the amount of milk produced in the early days after birth is directly related to the intensity of nipple stimulation. Researchers from the United Kingdom used a randomized control trial enrolling >100 women to compare mother–infant interactions depending on whether the infant was sleeping in the same bed or beside it in a cot or a crib. Feeding frequency was found to be five times higher in the bed as compared to the cot condition and in addition, they observed a 20% difference in the proportion of mothers still breast-feeding their babies after 2 weeks (Ball in Elton and O'Higgins, 2008). Although more research has to be carried out, the study makes the case for rethinking current postnatal ward practices.

Public Health and Health Behavior Change

Standard public health campaigns aimed at preventing harmful behavior such as sun bathing or smoking usually focus on education and knowledge of the health consequences of behavior. The premises of those interventions are that unhealthy, irrational behavior results from a lack of information. However, the impact of such campaigns does not appear to be sufficient to lead to significant behavioral change. More recently, approaches from the field of evolutionary psychology have led to promising results. The rationale is that psychology is particularly sensitive to short-term social benefits as opposed to long-term health risks. Social motives and the desire to appear more attractive are indeed related to a number of health-related problems such as skin cancer, substance abuse, and eating disorders. The insight from an evolutionary approach here resides in the consideration that natural selection favors any heritable (psychological) behavior that increases reproduction over long-term health. Using this perspective, a study recruiting 147 college students followed change in the intentions for sun tanning after receiving a workbook describing the appearance-damaging effect of sun tanning. After 'treatment,' tendency to sun tan indoors was reduced by over 50%, a self-reported change that was still present 2 months after the intervention (**Figure 5**; Hillhouse and Turrisi, 2002). Although the study had some limitations (self-report, only 2 months follow-up), its impact on behavior is far more significant than that of any other interventions. Sun tanning is marketed as being glamorous and increasing attractiveness yet it greatly increases the risk of skin

Figure 4 Correlation between serum bilirubin in premature neonates and antioxidant potential during the first week of life. Adapted from Hammerman, C., Goldstein, R., Kaplan, M., Eran, M., Goldschmidt, D., Eidelman, A.I., Gartner, L.M., 1998. Bilirubin in the premature: toxic waste or natural defense? Clinical Chemistry 44(12), 2551–2553.

Figure 5 An appearance-focused intervention on sun tanning behavior. The graph depicts changes in indoor tanning behavior (e.g., number of indoor tanning visits reported for the previous 2 months) as a function of treatment group preintervention versus 2-month follow-up. Treatment consists in receiving a workbook describing the appearance-damaging effect of sun tanning. Adapted from Hillhouse, J.J., Turrisi, R., 2002. Examination of the efficacy of an appearance-focused intervention to reduce UV exposure. Journal of Behavioral Medicine 25(4), 395–409.

cancer. To tackle the problem, an 'R UV UGLY' campaign has been introduced in 2011/12 by Cancer Research UK. We are yet to assess the impact of this appearance-based intervention on sun tanning behavior, but it is stimulating for other initiatives targeting behavior that are both social and health damaging. For instance, how about changing 'Smoking Kills' to 'Smoking makes you Ugly' on cigarette packaging?

Summary

EM is a young, promising, and burgeoning science that offers a number of concepts and methods to both rethink current medical practices and devise new diagnostic and therapeutic tools. EM is increasingly interacting with other scientific fields such as neuroscience, genetics, physiology, psychiatry, and developmental studies, but its role in everyday practice remains marginal and it is not yet included in the medical curriculum of most universities. Indeed, EM does not offer ready-made answers to health professionals and patients. Its main insight is in challenging the way we think about diseases, pointing out that treating symptoms without an understanding of their ultimate causes might no longer be satisfactory if we are to make significant progress in improving health care. EM still has a long way to go, however, as research remains more theoretical than applied and more advanced in some medical subfields (e.g., pediatrics) than others (e.g., cardiology). Only time will tell the full impact of this complementarity approach on medical practice and global health.

Abstract

Evolutionary social psychology is a framework that relies on principles of evolutionary theory to bridge various subdisciplines of psychology with other social sciences. From an evolutionary perspective, regularities in human social behavior reflect adaptive mechanisms designed to help our ancestors survive and reproduce. A number of different social psychological topics have been studied from an evolutionary perspective, including mating choice, aggression, altruism, and social cognition. Methodological approaches have included cross-cultural and cross-species comparisons, but the framework provides a basis for a range of experimental studies. Evolutionary psychologists assume that research on any topic in social behavior could benefit from an evolutionary perspective, and that other areas of psychology, including personality, psychopathology, and cognitive neuroscience, are all linked by this perspective. At the broadest level, the behaviors of humans and other animals are linked by general principles such as inclusive fitness, sexual selection, and differential parental investment. The field has been controversial, challenging traditional social science views, and it has been the subject of several misconceptions based on confusion about genetic determinism.

In 1908, McDougall's *Social Psychology* adopted an evolutionary perspective, following Darwin's (1872) suggestion that human social behaviors (including smiles, sneers, and other emotional expressions) were based in dispositions that helped our ancestors survive and reproduce. Evolutionary theory is founded on the idea of natural selection – that characteristics increasing chances of survival and reproduction proliferate because their bearers have more successful offspring. Characteristics well-suited to particular environmental demands are called adaptations. Evolutionary social psychology involves a search for evidence of adaptive mechanisms linked to human interaction.

Although people vary among themselves, both within and between cultures, certain regularities recur in human social interactions the world over. Members of all human groups communicate using complex spoken language, and share emotional expressions such as smiles and sneers, for example. Some social behavior patterns are unique to humans, some we share with many other species – the strong bonds between mammalian mothers and offspring, for instance. Similarly, other animals with slow-developing young often have biparental care of offspring, and other animals that live in small groups tend to have dominance hierarchies.

General Principles Applying across Species

Evolutionary theorists search for principles applying across animal species. *Differential parental investment* refers to differences between parents in the amount of resources invested in offspring (Trivers, 1972). As either sex increases investment in offspring, they become more selective about choosing mates. Members of the other sex consequently compete to be chosen. In mammals, females have an initially high investment (due to internal gestation and nursing). Because females in most mammalian species contribute substantially to offspring, they are in a position to choose among males demonstrating relatively superior health, attractiveness, or dominance. Hence, mammalian males, compared to females, tend to fight more among themselves, to be physically larger, and to possess more ornaments such as antlers. *Sexual selection* occurs when features are transmitted to offspring because they confer advantages in attracting the opposite sex (as in peacocks' feathers), or in competing with the same sex (as in rams' horns).

A central principle is *inclusive fitness maximization* – the idea that animals are designed not simply to survive and produce their own offspring, but to increase the probability their genes make it into future generations. Inclusive fitness explains many instances of apparently self-sacrificing behavior in animals. Ground squirrels who spot predators are more likely to make alarm calls if neighbors are closely related (Sherman, 1981). By slightly increasing their own risk, humans and other animals can gain a net genetic benefit – saving other individuals with copies of their genes.

Application to Human Social Behavior

Evolutionary theorists mine these broad principles for insights about human behavior, and to make predictions about circumstances under which people will be more or less likely to manifest aggression, altruism, or courtship behaviors. For example, men are slightly larger than women and reach reproductive maturity at a later age. Women commit substantially fewer homicides or assaults than men, and male violence is predominantly directed at other males. Across animal species, these are hallmarks of differential parental investment and polygyny. Of 849 societies in the cross-cultural area files, polygyny (one male and multiple females) was either usual or occasional in 708, polyandry (one female and multiple males) was found in only four, and the remaining 137 were exclusively monogamous (Daly and Wilson, 1983). Further, the circumstances associated with these variations follow principles found in other species (Daly and Wilson,

1983; Crook and Crook, 1988). For example, polyandry often involves brothers (who share genetic interests) living in resource-poor environments. Steep polygyny (as in harems) is found in circumstances of relative abundance, steep social hierarchy, and occasional famine (so a female's offspring have a better chance of surviving if she chooses an already married man from a wealthy powerful family over a single poor man). Although polygyny was an option across societies, most marriages are monogamous, because only highly successful men attracted multiple wives. Hence, ancestral males invested most of their reproductive effort in the offspring of a small number of women (often one). As a consequence, human males are selective about long-term mates, and females will compete with one another for desirable males (Buss, 1999; Kenrick and Trost, 1993).

Cross-Cultural Data

Because all human groups involve some common demands, evolutionary theorists assume that people the world over, despite cultural and ecological differences, share common human characteristics. Cross-cultural data reveal some general patterns consistent with principles of differential parental investment and sexual selection (Kenrick and Trost, 1993). Adult males have killed one another many times more frequently than adult females in societies ranging from hunter-gatherers in remote jungles to urbanites in modern Asia and Europe, as far back as historical data are available (Daly and Wilson, 1988). Likewise, women across societies place more emphasis than men on potential mates' resources and status (Buss, 1999).

Other data on mate selection reflect a unique feature of human biology – females reach sexual maturity earlier than males, show a fertility peak in the twenties and early thirties, and then completely cease reproduction despite many remaining years of life. Consistent with this difference in reproductive lifespan, women are attracted to mates several years older than themselves, whereas men change relative preferences as they age. Young men are attracted to women their own age or older; older men prefer women much younger than themselves (Kenrick et al., 1996). These patterns are found around the world, with somewhat stronger sex differences in societies in which women begin reproducing earlier (Kenrick and Keefe, 1992).

Experimental Data

Evolutionary principles can be used to generate experimental predictions. Experiments are not designed to test basic assumptions about natural selection, but to use the general principles as heuristics. For example, one team of researchers used inclusive fitness theory to generate predictions about helpfulness towards individuals varying in genetic relatedness (Burnstein et al., 1994). Experimental scenarios described helping situations ranging from small errands to rescuing someone in a burning building. For everyday helping, norms of politeness buffered discrepancies based on kinship and reproductive potential (grandmother was more likely to be helped than younger sister, for example). In life or death situations, however, help was focused more on closely related individuals with high reproductive potential (younger sister compared to grandmother or cousin, for example). Another series of studies examined how sex differences in mate selection criteria affect perceptual processes related to judgments of oneself and potential mates (Gutierres et al., 1999; Kenrick et al., 1994). Women rated commitment to male partners lower after exposure to socially dominant, but not physically attractive, men, whereas men's commitment showed the opposite effect. Conversely, women's self-ratings of their mating desirability were diminished more by physically attractive than by socially dominant women, with men's self-ratings showing the opposite effect (diminished by dominant, but not physically attractive men).

History and Future Directions

McDougall's (1908) *Social Psychology* assumed human social 'instincts.' The position was much misunderstood and abandoned without an empirical legacy. Decades later, European ethologists began successfully applying evolutionary models to social behaviors of nonhuman animals. In 1975, E.O. Wilson made a controversial suggestion that 'sociobiology' (the evolutionary analysis of animal social behavior) would eventually encompass the social sciences. This stimulated social psychologists to consider empirical applications to their field (e.g., Cunningham, 1981). Part of the controversy about the approach stemmed from misunderstandings about genetic determinism. Human social behaviors vary across contexts and cultures, and social scientists assumed sociobiology implied rigid instincts insensitive to environments. Some protested that evolutionary hypotheses were untestable, or required researchers to study genetic biology or archaeology. Evolutionary theorists clarified that environmentally insensitive instincts based on deterministic genes are misconceptions, hardly relevant to invertebrates, much less to mammals (e.g., Alcock, 1998; Kenrick, 1995). The brains of complex animals contain not rigid programs, but environmentally sensitive psychological mechanisms (Buss and Kenrick, 1998; Kenrick et al., 1998; Tooby and Cosmides, 1992). Questions about testability were addressed with empirical data and competing evolutionary hypotheses (e.g., Graziano et al., 1997; Gangestad and Thornhill, 1997). The position remains controversial, but has moved towards mainstream empirical science (e.g., Buss, 1999; Crawford and Krebs, 1998; Simpson and Kenrick, 1997). Evolutionary psychologists assume the perspective could enrich research on any topic in social behavior, and that other areas of psychology including personality, psychopathology, and cognitive neuroscience are all linked by this perspective. Although the implications for mating behaviors and sex differences have been most thoroughly explored, evolutionary models have implications for understanding kinship and family relationships, intergroup relations, and social cognition. Evolutionary psychologists believe the Darwinian perspective is as relevant to the study of human beings as it has been to the study of all other living species.

Abstract

Evolutionary sociology (alternatively known as biosociology) is a new area in sociology that covers a wide range of topics, from microsociological to macrosociological, with the unifying feature being an acknowledgment of the role of evolved human biology in social life and hence an incorporation of biological factors into sociological scholarship. The field focuses on how evolved human biology interacts with particular social environments to simultaneously both produce, and respond to, social institutions and structures. In this article, I review the six major strands of research within the evolutionary sociology area.

Introduction

Evolutionary sociology (alternatively known as biosociology) is an area that has emerged relatively recently in sociology, and its emergence has not been without controversy. However, in the last 10 years the number of publications in the area has increased dramatically, and an Evolution, Biology and Society Section of the American Sociological Association was first created in 2004. The name evolutionary sociology covers a wide range of topics, from microsociological to macrosociological, with the unifying feature being an acknowledgment of the role of biology in human social life and hence an incorporation of biological factors into sociological scholarship. The field focuses on how evolved human biology interacts with particular social environments to simultaneously both produce and respond to social institutions and structures. Researchers in the area use a variety of sociological methodologies, as well as research results and methodologies, from an array of disciplines including anthropology, behavioral genetics, history, primatology, paleoanthropology, biology, psychology, and neuroscience. What follows discusses the background to the area and reviews six major strands of research within the evolutionary sociology field: (1) emotions and social behavior, (2) neurosociology, (3) evolution and social behavior, (4) genes and social behavior, (5) hormones and social behavior, and (6) societal evolution.

Background to the Field

The 1970s controversy over sociobiology (see Segerstråle, 2000 for details) percolated into sociology in the late 1970s, with sociologists such as Pierre van den Berghe and Joseph Lopreato becoming vocal proponents (van den Berghe, 1974; Lopreato, 1984). However, sociobiology was resoundingly rejected by the vast majority of sociologists, and by the 1990s had largely disappeared from the field (Machalek and Martin, 2004). It took root in anthropology, where anthropologists such as Napoleon Chagnon, Sarah Hrdy, David Barash, Monique Borgerhoff Mulder, Laura Betzig, Richard Alexander, William Irons, and others became leading proponents. In the late 1980s a revised form of sociobiology known as evolutionary psychology was born, with early leading proponents including the psychologist Leda Cosmides and the anthropologist John Tooby (Cosmides and Tooby, 1987). Evolutionary psychology took off as a subfield within psychology, and this change and the formation of the Human Behavior and Evolution Society invigorated the nascent evolutionary anthropology group. By the turn of the century, evolutionary psychology was well ensconced within the discipline of psychology, and an evolutionary anthropology section of the American Anthropological Association was formed. At about this time, the Evolution, Biology and Society Section of the American Sociological Association became a section in formation and a home for evolutionary sociologists. At first the section was called Evolution and Sociology. Later, as scholars studying the interaction between genes and social behavior joined the section, the name was changed to Evolution, Biology & Society.

Evolutionary sociology, like sociobiology before it, remains controversial in sociology. Many of the same arguments originally made against sociobiology are leveled against evolutionary sociology. An early critique of sociobiology is that in the past biology has been used to support the prejudices of the researcher and/or to support the existing social status quo (see Gould, 1981 for a review of this problematic work). For example, biology was used by social Darwinists in the early twentieth century to justify and explain existing social inequalities between groups. It should be noted that current evolutionary sociologists distance themselves from the prejudices, faulty reasoning, and methods that characterized much of this earlier work. The evolutionary view is that all individuals share the same universal biology and evolutionary legacy. This is buttressed by the finding that there is more genetic variation within groups than between groups (Witherspoon et al., 2007).

Other criticisms include the charge that the evolutionary or biosocial approach is reductionist (Rose, 2000) and unnecessary (Heuveline, 2004). Yet many sociologists acknowledge that there is a need for models of individual behavior (hence reductionism) in sociology (Crippen, 1994; Whitmeyer, 1994; Kiser, 1996; Massey, 2002, 2005; Lovett, 2006). Others claim that evolutionary/biosocial approaches embrace genetic determinism, or that scholars in the area fail to give evidence in support of their claims. Much of this is based on a misunderstanding of evolutionary approaches (Machalek and

Martin, 2004) and a lack of knowledge of research findings in the area, particularly in neighboring disciplines to sociology such as anthropology, psychology, and biology.

Yet the tide may be turning. Freese et al. (2003) was a watershed piece, a well-cited mainstream sociological publication advocating the incorporation of biology into the discipline. Early biosociologists such as Booth et al. (2000) had previously written a review of research on biosocial influences on the family, a follow-up was published by D'Onofrio and Lahey (2010). The introduction of biosociology into the mainstream was fully established by the publication of special issues on biosociology in two of the three major journals in the field: *Social Forces* in 2006 and the *American Journal of Sociology* in 2008. Guang Guo (2006) edited the special issue of *Social Forces*, and Peter Bearman (2008) edited the special issue of the *American Journal of Sociology*.

It is notable that many of these authors included in these special issues have particularly been proponents of examining genetic influences on behavior and have therefore largely sidestepped evolutionary questions. Yet genes, as are all biochemicals and in fact everything in biology, are products of evolution (Dobzhansky, 1973). Genes and social behavior are just one subarea within evolutionary sociology as it currently exists within sociology. The other subareas are emotions and social behavior, neurosociology, evolution and social behavior, hormones and social behavior, and societal evolution.

Emotions and Social Behavior

Jonathan Turner was an early proponent of evolutionary sociology, and much of his work has dealt with the sociology of emotion. He and coauthors have argued for the centrality of emotions in human actions, and they make the case for the grounding of human emotions in biology (Turner, 2007; Turner and Maryanski, 2005, 2008; Turner and Stets, 2006). Douglas Massey (2002) in his presidential address at the meetings of the American Sociological Association suggested that the evolution of human society and human cognition illustrates the creation and workings of the human emotional brain and the fact that it operates independently of, but strongly influences, the rational brain.

Turner and Maryanski (2008) in a work based on information from primatology, behavioral ecology, and paleoanthropology draw a picture of the evolved human that emerged some 150 000 years ago and has changed little since: an individualistic hominid, emotionally tied to group members, but resistant to domination by other hominids. They note that this is the human nature that cultures have built on but not eradicated.

Besides work on how individual emotions influence social relations, there are other scholars within this group who examine the reverse: how social relations and situations in turn influence emotions (Stets and Asencio, 2008; TenHouten, 2005). Robinson et al. (2004) discuss how experience in group interactions of being high and low status influences emotional and physiological states. Much of the research shows that occupying a low status position is more stressful than occupying a high status position. Similarly, Massey (2004) theorizes that exposure to stress leads to a variety of deleterious health and cognitive outcomes for African Americans (see also Davis and Were, 2008).

Neurosociology

Authors in the subarea of neurosociology argue for the linking of social psychology and social neuroscience. This is another emerging area, spearheaded by David Franks and Thomas Smith (Franks and Smith, 2009; Smith, 2004). A didactic session on the area was held at the Annual Meetings of the American Sociological Association in 2010.

David Franks and others (Franks, 2010; Hammond, 2004) draw on the neuroscience of emotion and cognition. Their research draws on findings from research using fMRI scanners and PET scans to examine which parts of the brain are used for cognition and emotions. They examine the role of emotions in social behavior, unconscious behavior, the role of mirror neurons in imitation and empathy, and the brain bases of the social self. Findings include the importance of normal social interactions for the development of the individual brain and the development of the self. Another finding is the fact that the large majority of what the brain does, perhaps as much as 80%, is unconscious to the individual. Last, contrary to many beliefs, emotion is the basis of rational decision making. For people to make sensible decisions, the available choices must have an emotional valence. When that emotional valence is missing, for whatever reason, the person cannot make rational decisions.

Franks (2010) notes that research on mirror neurons support the work of the Chicago pragmatists. Mirror neurons are neurons in the brain that mimic the neurons of others. So when a person falls and feels pain, neurons in his or her brain fire, and the same neurons in the brain of the person witnessing the event also fire. This means that to a certain extent the witness actually feels the fallen person's pain. As a result, mirror neurons are importantly involved in empathy. They are also involved in helping individuals see how others see them, and this is an important component of the development of self-identity and self-esteem. This is the mechanism for what Charles Horton Cooley referred to as the "looking glass self" (Franks, 2010). Other neurosociologists show how other social processes are based on the existing neural wiring of the human brain. For example, Hammond (2004) shows how other social experiences such as religious experiences piggyback on neural circuits evolved for different purposes.

Evolution and Social Behavior

This is probably the least well-accepted subtopic within evolutionary sociology in the mainstream of sociology. Pierre van den Berghe was one of the first sociologists working in the area, and he found little audience within sociology (van den Berghe, 1979, 1990). More recently there has been much greater acceptance of the evolutionary approach to human social behavior in sociology both in the United States and abroad (Whitmeyer, 1994, 1997; Lopreato and Crippen, 1999; Machalek and Martin, 2004; Sanderson, 2001, 2008; Runciman, 2008; Lacerda, 2009; Hopcroft, 2008, 2009 a,b). These authors all argue for a linkage of theory and research in sociology with theory from

evolutionary biology. Many of them deal with resistance among sociologists to this kind of thinking, as well as erroneous ideas about the nature of the area.

The first evolutionary approach to the family within sociology was the book *Human Family Systems* (van den Berghe, 1979), a complete review of human family systems in all known human societies and how they can be explained by an evolutionary perspective. van den Berghe notes the centrality of kin processes in all societies, as well as commonalities in mate choice and parenting across societies. For example, in all human societies women marry men who are older than they are, on average, although the age gap varies across cultures. In all human societies women assume the majority of child care. Since then, prominent work in the area has been done by family demographers (Biblarz and Raftery, 1999) who found the counterintuitive finding that single mothers are better at sponsoring the attainment of their children than reconstituted families.

Work by Hopcroft (2006), Fieder and Huber (2007), and Nettle and Pollet (2008) has refined our understanding of the relationship between status and fertility, showing that income earned by men is positively related to their fertility in advanced industrial societies, while income earned by women is negatively related to their fertility. There has also been research testing evolutionary hypotheses concerning investment in children. Hopcroft (2005) tested the Trivers–Willard hypothesis that high-status parents would invest more in sons, and low-status parents would invest more in daughters, and found support for the hypothesis – finding that sons of high-status parents received more years of education than daughters, and daughters of low-status parents received more years of education than sons. Freese and Powell (1999) tested the hypothesis by examining parental investments in adolescents and found no support for it. Hamilton et al. (2007) tested the evolutionary hypothesis that biological children would receive more investment than nonbiological children. They found this was not true in the case of adoptive children, although others have found it is true of stepchildren (Henretta et al., 2012).

Evolutionary biology posits sex differences, particularly in parenting behavior, with women being the more committed parents (Rossi, 1984). This has implications for many social phenomena, including inequality between the sexes (Huber, 2007; Hopcroft, 2009a). There are other sex differences that likely have an evolved, biological component, for example, the sex difference in depression (Hopcroft and Bradley, 2007). Ellis et al. (2008) have published a comprehensive list of sex differences, many of which likely have an evolutionary origin.

The potential contributions of evolutionary theory to sociological theory have been explored in different ways by a number of authors. Blute (2006, 2010) examine the possibility of using models from evolutionary biology to model cultural evolution (see also Mark, 2011). Sanderson has argued that materialist theories need help from evolutionary theories (see Sanderson, 2001, 2007; see also Horne, 2004). Hopcroft (2008, 2009b) has suggested that evolutionary theory can help create a unifying paradigm for sociology. In Europe a prominent proponent of the use of evolutionary theory in sociology is the Finnish sociologist J.P. Roos (see Roos and Rotkirch, 2005).

There is much interest in the evolutionary origins of religion in neighboring disciplines of anthropology and psychology. Sociologist Steven K. Sanderson (2008) has recently joined this enterprise. He suggests that the universal existence of religion across all human societies is because during the human evolutionary period religiosity was an adaptive trait. Although not specifically evolutionary, Miller and Stark (2002) suggest that gender differences in risk aversion (possibly an evolved trait) play a role in the sex difference in religiosity. Collett and Lizardo (2009) debate this point. Regarding crime, Ellis notes that universally young men are more involved in crime than any other group (Ellis, 2004, see also Savage and Vila, 2003). Ellis argues that there are evolutionary reasons to explain this. Last, one of the pioneers of the evolution and social behavior area, Pierre van den Berghe, has also explored the evolutionary bases of ethnic behavior (van den Berghe, 1981). A follow-up to this work was published by a student (Whitmeyer, 1997).

Genes and Social Behavior

Scholars in this area argue for an incorporation of genetic effects on behavior in sociological research. Shanahan et al. (2010) urges sociologists to join the research effort to examine the joint effects of genes and environmental contexts on social behavior. Conley (2009) and Guo et al. (2009) describe methods for including genetic information into social science research. Much of this research relies on the collection of DNA data as well as the more typical survey data in sociological data sets. An important data source is the National Longitudinal Study of Adolescent Health (Add Health), a study designed by Peter Bearman and Richard Udry, both at the time members of the Department of Sociology at the University of North Carolina at Chapel Hill.

This research has examined the relative influence of social contexts and genes on substance abuse (Button et al., 2009), drinking behavior (Pescosolido et al., 2008), and smoking (Boardman et al., 2010). Other research examines the role of biological potential and environment on income attainment (Conley and Bennett, 2001), educational attainment (Shanahan et al., 2008), and intellectual development (Guo and Stearns, 2002).

There are also a variety of studies that examine the interaction of genes and social contexts on physical and mental health (Adkins et al., 2008; Pescosolido et al., 2008; Kendler et al., 2011). Others have examined the relative effects of genes on happiness (Schnittker, 2008) and attitudes (Eaves et al., 2008). Using Add Health data, criminologist Kevin Beaver (Beaver, 2008; Beaver et al., 2008; Vaughn et al., 2009), as well as sociologist Guang Guo (Guo et al., 2008a), have examined the interaction between genes and environment on criminal and delinquent behavior.

Other researchers look at the gene–environment interactions for outcomes such as same-sex attraction (Bearman and Brückner, 2002), number of sexual partners (Guo et al., 2008b), age at first intercourse (Guo and Tong, 2006), and fertility behavior (Kohler et al., 1999, 2002). Powell et al. (2010) examine Americans' beliefs about the role of genes in same sex attraction and how this affects their opinions about same sex couples.

All these studies typically find both a substantial genetic effect and a gene–environment interaction on the social outcome being studied. One general finding that emerges

from a number of these studies is that genetic influence on behavior is stronger during affluent time periods when individuals (presumably) have more choice. This has been capitalized on by Nielsen (2006), who suggests that the degree to which an individual achieves their genetic potential can reflect the opportunities present in their society (see also Adkins and Vaisey, 2009). Although this generally rises with affluence, there is variation in such opportunities across developed societies.

Besides this work on gene–environment interactions, other scholars focus on epigenesis – how gene expression is regulated by the environment and how changes in gene expression can even be passed on to future generations (Lock, 2009; Niewohner, 2011; Singh, 2012; Spector, 2012). These studies stress the malleability of the organism and its development in response to environmental context.

Hormones and Social Behavior

Alan Booth has been a pioneer in sociology at including biomarkers such as testosterone in social science research in the family. His article with coauthors (Booth et al., 2006) both reviews research and advocates for continued research on testosterone's role in social behavior. These researchers use hormonal analysis of saliva samples and statistical methods. Findings show that many important social phenomena are a product of the interaction of social contexts with individual hormonal states (Mazur, 2004; Booth et al., 2008). Much of the research has been on the effects of testosterone. Of this research, most has been on the effects of testosterone in boys and men (Mazur and Booth, 1998; Dabbs and Dabbs, 2000; Updegraff et al., 2006). There have been comparatively fewer studies of the effects of testosterone on girls and women (Udry, 2000; Booth et al., 2005). Much of this research has been highly controversial within sociology, particularly when it pertains to sex differences in behavior (e.g., see Miller and Costello, 2001; Risman, 2001 for critiques of Udry, 2000).

Societal Evolution

The last subarea within the field of evolutionary sociology is a macrosociological area that examines large-scale societal change and the evolution of human societies. Gerhard Lenski, the pioneering scholar in this area, was the first to note the importance of subsistence technology in shaping social arrangements and the degree of social stratification (Lenski, 1984, 2005). Lenski's conclusions that a society's subsistence technology (hunting and gathering, horticulture, plow agriculture, or industrial technology) predicts their population (size), social organization, and ideology is well known and much used. The association of complexity of subsistence technology with complexity in occupational and political structures is also well known. Lenski (1984) finding that social inequality increases with increased complexity of subsistence technology until we reach industrial societies has also been widely recognized (Nielsen, 2004). Others note the implications of subsistence technology for gender stratification. While the amount of gender stratification in society generally tracks the degree of stratification in general, Blumberg (2004) suggests that the most important factor influencing gender stratification in a society is women's relative control of key economic resources. Women are more likely to have a higher status in societies where they contribute to the society's main productive activities, but women's work does not enhance gender equality unless it also results in control of significant economic resources.

Lenski and Nolan (2005) hypothesized that currently developing societies that were previously agrarian do better in terms of various measures of development than societies that were previously horticultural. The hypothesis is empirically strongly supported. Lenski's Ecological Evolutionary Theory (2005) also has implications for the failures of Marxist society. The failure of Marxist societies in Lenski's view is due to the failure of Marxism to fully understand human nature. Marxist societies ended with a concentration of power at the top, so Communist societies more closely resemble the monarchies and oligarchies in agrarian societies.

Unlike Lenski, who focuses on internal characteristics of societies for explaining societal evolution, other authors link the process of societal evolution primarily to the society's place in the modern world system and adopt a world system's theoretical perspective (e.g., Chase-Dunn, 2005). Thomas Hall and coauthors (Hall and Fenelon, 2009) have looked at the distinctiveness of indigenous movements and how they have responded to recent policy reforms and globalization. Findings from this research highlight the importance of the influence of global and historical forces on indigenous movements.

Conclusion

Evolutionary sociology is a fairly recent field within sociology but has become home to a group of scholars working in a variety of subareas. Of these, the most prominent are the scholars that study the interaction of individual genetic potential with social environments on social outcomes. As more information on the role of biology in social phenomena emerges, the discipline as a whole is likely to lose its biophobia and begin to more fully embrace work that examines the evolutionary origins of human biology.

Evolutionary Theory, Structure of

Elisabeth Lloyd, Indiana University, Bloomington, IN, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Charles Darwin proposed a general type of natural selection model that could explain a variety of particular cases of adaptation to local environments, once details of organismic traits and selection pressure were inserted. Much of evolutionary theory today, though not all, is represented through mathematical models, especially through the models of population genetics, of the evolution of states of a given system, both in isolation and interaction through time. This article discusses in detail various ways to describe the evolutionary models that make up evolutionary theory. The main items needed for this description are the model types of natural selection, drift, and so forth, most often described through the definition of a state space, state variables, parameters, and a set of laws of succession and coexistence for the system. Choosing a 'state space' (and, thereby, a set of state variables) for the representation of genetic states and changes in a population is a crucial part of population genetics theory. Claims about evolutionary models may be confirmed in three different ways: (1) through fit of the outcome of the model to a natural system; (2) through independent testing of assumptions of the model, including parameters and parameter ranges; and (3) through a range of instances of fit over a variety of the natural systems to be accounted for by the model, through a variety of assumptions tested, and including both instances of fit and some independent support for aspects of the model.

The Structure of Darwinian Evolutionary Models

The basic structure of Darwinian evolutionary models is deceptively simple and elegant; such simplicity can yield powerful change over the proposed time spans encountered by the biological systems involved. For evolution by natural selection, for example, we start with a basic very general model structure that includes a set of assumptions or components (Griesemer, 1984; Lloyd, 1983; Van Fraassen (1980: p. 44) has defined 'model type' as the description of a structure in which certain parameters are left unspecified in this way). The classic selection model type concerns a population of varied organisms, and these variations are assumed to be at least partially inheritable. In this population's environment (which is always defined relative to the organism's needs and sensitivities), there are demands and stresses affecting some variants more than others, resulting in differential reproduction. Thus, the basic natural selection model type leads to the change in the population variants' composition and structure over evolutionary time. (For discussion of multilevel selection model types, see Lloyd, 2012.) In 1859, Charles Darwin, in *On the Origin of Species*, proposed his basic abstract selection model type, and other evolutionary model types, and also filled in their details in various cases in various ways in the book and his correspondence; in this manner, he illustrated how to use and apply the models (*see* Darwinism).

More specifically, each of the model types serve as formats for explanation; the particular terms or factors in a model type vary in each application, depending on the outcome of the model and various assumed conditions (Griesemer, 1984; Lloyd, 1983). For example, in the *Origin*, Darwin needed evidence for his assumption that wild organisms spontaneously developed heritable variations some of which would be advantageous to their survival and reproduction. Such a general assumption of the existence of useful variations was necessary for a variable in the natural selection model type, which would then be instantiated in specific models by individual cases of variation. Darwin found empirical evidence for this assumption in the animal breeders' information, as he presents in the *Origin*. (Darwin kept up an avid and long-term correspondence with a number of pigeon breeders, from whom he learned detailed information about the vast variety of feather form, pattern, and color, as well as behaviors that spontaneously arose in their pigeons.) Elsewhere in his correspondence, Darwin also offers evidence to support an empirical assumption of a specific model constructed using the selection model type. In looking at wingless insects that appear on oceanic islands at a higher concentration than elsewhere, Darwin proposed to explain their frequency by a selection pressure of high winds blowing them off the islands, thus favoring insects without wings. He tested this model assumption by comparing an even smaller island to the other islands he was examining earlier: he found, as he predicted, an even higher percentage of wingless insects. His earlier assumption of a selection pressure was thus indirectly confirmed in his proposed model (Beatty, 1980: p. 401; Lloyd, 1983: pp. 121–122; Thompson, 1983: pp. 226–227). Section Confirming and Testing Models below provides a more detailed discussion about the confirmation of evolutionary models.

Note that the evolutionary selection models can range from the very abstract and general model structure with its high level assumptions, through to ever more specified models as we identify and fill in the necessary assumptions of selection pressures, types of variation, and evidence for heritability. Ultimately, our ever more detailed specifications of the assumptions result in a fully specified selection model, which anchors the most concrete end of the model continuum, from the most abstract model type to the most concrete model (Beatty, 1980: pp. 412–413; Griesemer, 1984: pp. 106–107; Lloyd, 1983: pp. 118–119).

The Structure of Population Genetic Evolutionary Models

While Darwin's evolutionary models and explanations were nonquantitative, much of evolutionary theory at the beginning of the twenty-first century is represented through mathematical models or equations of population genetics, which specify the evolution of states of a given system, both in isolation and interaction, through time. This is done by conceiving of the evolutionary model as capable of a certain set of states, with these states represented by elements of a certain mathematical space, the state space (Beatty, 1980; Lloyd, 1988/1994; Thompson, 1983). Generally speaking, 'models' and 'systems' always refer to ideal systems; when the actual biological systems are being discussed, they are called 'empirical' or 'natural' systems. The variables used in each mathematical model represent distinct measurable, or potentially quantifiable, physical/biological magnitudes. Classically, any particular configuration of values for these variables is a 'state' of the system, the 'state space' being the collection of all possible configurations of the variables.

The theory itself represents the behavior of the system in terms of its states: the rules or laws of the theory (i.e., laws of coexistence, succession, or interaction) can delineate various configurations and trajectories on the state space. A description of the structure of the theory itself therefore only involves the description of the set of models that make up the theory. In an application of the theory or models to the real world, we consider both 'data models' and the idealized models describing idealized systems and their resemblance. 'Data models' are simplified structures representing the natural world made up of measurements, observations, or the results of experiments; that is, numbers or values extracted from the real world, many of which are arranged in relations suggested by the theoretical models (Suppes, 1962). The ideal systems are usually gradually specified, as described in Section The Structure of Darwinian Evolutionary Models, to show a good match or similarity with the data models, to which they are compared during an application of the theory or model type (Giere, 1988; Van Fraassen, 1980).

Construction of a model within the theory involves assignment of a location in the state space of the theory to a system of the kind defined by the theory. Potentially, there are many kinds of systems that a given theory can be used to describe. Limitations come from the dynamical sufficiency (whether it can be used to describe the system accurately and completely) and the accuracy and effectiveness of the laws used to describe the system and its changes. Thus, there are two main aspects to defining a model. First, the state space must be defined, which involves choosing the variables and parameters with which the system will be described; second, coexistence laws must be defined, which describe the structure of the system, and laws of succession, which describe changes in its structure.

Defining the state space involves defining the set of all of the states the system could possibly exhibit. Certain mathematical entities – in the case of many evolutionary models, these are vectors – are chosen to represent these states. The collection of all the possible values for each variable assigned a place in the vector is the state space of the system. The system and its states can have a geometrical interpretation: the variables used in the state description (i.e., state variables) can be conceived as the axes of a Cartesian space.

The state of the system at any time may be represented as a point in that space, located by projection on the various axes. The family of measurable physical magnitudes, in terms of which a given system is defined, also includes a set of parameters. Parameters are values that are not themselves a function of the state of the system. Thus, a parameter can be understood as a *fixed value* of a variable in the state space – topologically, setting a parameter amounts to limiting the number of possible structures in the state space by reducing the dimensionality of the model.

Laws, used to describe the behavior of the system in question, must also be defined in a description of a model or set of models. Laws have various forms: in general, coexistence laws describe the possible states of the system, while laws of succession describe changes in the state of the system.

Let us discuss in more detail the description of the evolutionary models that make up current evolutionary theory. The main items needed for this description are the definition of a state space, state variables, parameters, and a set of laws of succession and coexistence for the system. Choosing a 'state space' (and, thereby, a set of state variables) for the representation of genetic states and changes in a population is a crucial part of population genetics theory. (Population genetics models are a highly technical, but not necessarily 'core,' part of evolutionary theory itself (Thompson, 1983)).

Paul Thompson suggests that the state space for population genetics would include the physically possible states of populations in terms of genotype frequencies. The state space would be "a Cartesian *n*-space where '*n*' is a function of the number of possible pairs of alleles in the population" (Thompson, 1983: p. 223). We can picture this geometrically as *n* axes, the values of which are frequencies of the genotype. The state variables are the frequencies for each genotype. Note that this is a one-locus system; that is, we take only a single gene locus and determine the dimensionality of the model as a function of the number of alleles at that single locus.

Another type of single locus system, used less commonly than the one described by Thompson, involves using single gene frequencies, rather than genotype frequencies, as state variables. Some of the debates about 'genic selectionism' center around the descriptive, dynamical, and parametric adequacy of this state space and its parameters for representing evolutionary phenomena (Dawkins, 1982; Lloyd et al., 2008).

With both genotype and gene frequency state spaces, treating the genetic system of an organism as being able to be isolated into single loci involves a number of assumptions about the system as a whole. For instance, if the relative fitnesses of the genotypes at a locus are dependent on other loci, then the frequencies of a single locus observed in isolation will not be sufficient to determine the actual genotype frequencies. Assumptions about the structure of the system as a whole can thus be incorporated into the state space in order to reduce its dimensionality. Lewontin (1974) offers a detailed analysis of the quantitative effects of dimensionality of various assumptions about the biological systems being modeled. Interactions between genotypes, and between one locus and another cannot be represented in a single locus model (with the exception of frequency-dependent selection), for the

simple reason that they involve more than one locus (Lewontin, 1974: pp. 273–281).

As far as the structure of the theory goes, although all single locus models should, in some sense, be grouped together, they are not all exactly the same model – each particular model has a different number of state variables, depending upon the number of alleles at that locus. Because a model type is simply an abstraction of a model, constructed by abstracting one or more of the models' parameters or variables, a single model can be an instance of more than one model type. This is an extremely important aspect of the flexibility of this approach to theory structure. Along similar lines, we may say that each model type can be associated with a distinctive state space type. In the preceding example, the single locus model is to be taken as an instance of a general state space type for all single locus models; that is, the different single locus model types are conceived as utilizing the same state space type. Alternatives, such as two-locus models, must be taken as instances of a different state space type.

'Parameters' are the values that appear in the succession and coexistence laws of a system that are the same for all possible states of the defined system. For instance, in the modification of the Hardy–Weinberg equation that predicts the frequencies of the genotypes after selection, the selection coefficient, s, or multiplier, appears as a parameter in the formula

$$p^2AA + 2pqAa + (1-s)q^2aa = 1 - sq^2.$$

There are a variety of methods of establishing the value at which a parameter should be fixed or set in the construction of models for a given real system; for example, simulation techniques can be used to obtain estimates of biologically important parameters. In some contexts, maximum likelihood estimations may be possible. Parameters can also be set arbitrarily, or ignored. This is equivalent to incorporating certain assumptions into the model for purposes of simplification (Levins, 1968: pp. 8, 89).

One expects the values of parameters to have an impact on the system being represented; but variations in parameter values can make a larger or smaller amount of difference to the system. For instance, take a deterministic model that incorporates a parameter for mutation, μ. The rates of change of this model are virtually insensitive to realistic variations in the value of the mutation parameter, μ. Yet the selection parameters play a crucial role in this same model. A very small amount of selection in favor of an allele will have a cumulative effect strong enough to replace other alleles (Lewontin, 1974: p. 267).

Population size is another case in which the value assigned to the parameter has a large impact on the model results. The parameter for effective population size, N, can play a crucial role in some models, because selection results can be quite different with a restricted gene pool size (Mayr, 1967: pp. 48–50). In many of the stochastic models involved in calculating rates of evolutionary change, the resulting distributions and their moments can depend completely on the ratio of the mean deterministic force to the variance arising from random processes (Lewontin, 1974: p. 268). This variance is usually proportional to $1/N$ and is related to the finiteness of population size. Thus, change in the value of the single parameter, N, can completely alter the structure represented by the theory.

The choice of parameters can also make a major difference to the model outcome. Theoreticians have choices about how to express certain aspects of the system or environment. The choice of parameters used to represent the various aspects can have a profound effect on the structure, even to the point of rendering the model useless for representing the real-world system in question. Group selection models provide a case in which choice of parameters not only alters the results of the models, but also can lead to the near disappearance of the phenomenon being modeled (Wade, 1978).

Some authors, when discussing genetic changes in populations, speak of the system in terms of a type of state space involving phenotypes. This makes sense, because the phenotype determines the breeding system and the action of natural selection, the results of which are reflected in the genetic changes in the population; quantitative genetics is the set of models that concentrate on phenotypic state spaces. In his analysis of the structure of population genetics theory, Lewontin (1974) traces a single calculation of a change in genetic state through both genotypic and phenotypic descriptions of the population.

But in addition, mating patterns, and probabilities of survival and reproduction, although influenced by genes, are a consequence of developmental events that are contingent on the environment of the developing organism, and involve more than any simple phenotype. In the most general case, environment includes influences of the phenotypes of previous generations by means of cytoplasmic inheritance through the egg. A complete general representation of genetic evolutionary processes then requires not two, but six spaces with sequential transitions within them and mappings from one to the other (Lloyd et al., 2008). Haploid spaces represent only the single chromosome or set of one sex's genes, while (sexually reproducing) diploid state spaces represent both sets. The complete set of six spaces, S, is thus:

S_1, a diploid phenotypic space;
S_2, a diploid genotypic space;
S_3, a diploid pair phenotypic space;
S_4, a diploid pair genotypic space;
S_5, a haploid phenotypic space; and
S_6, a haploid genic space.

(Assuming that organisms reproduce in discrete generations, with no overlap between generations.) While it is true that the system's transition from one generation to the next may be represented in any one of the six spaces, we need to know the entire loop – and all the parameter values in each of the model stages in that loop – in order to obtain a fully accurate representation of any chosen state space in the next generation, that is, to get the state transformation equation between generations *within any one of the spaces* (e.g., if we want to move from (S_6) to (S_6 in the new generation)). For instance, for the transition in allelic space, we must move out of that space, into genotypic space to define the fitness parameters, and back into allelic space in order to characterize the next generation (Lloyd et al., 2008: pp. 143–144).

Now consider a few particular aspects and forms of the 'laws' used in population genetic models. The most obvious differences, in laws as well as in state space types, are between deterministic and stochastic models. Coexistence laws describe the possible states of the system in terms of the state space. In the case of evolutionary theory, these laws would consist of

conditions delineating a subset of the state space that contains only the biologically possible states. Laws of succession describe changes in the state of the system. In the case of evolutionary theory, dynamic laws concern changes in the genetic composition of populations.

The laws of succession select the biologically possible trajectories in the state space, with states at particular times being represented by points in the state space. The law of succession is the equation of which the biologically possible trajectories are the solutions. The Hardy–Weinberg equation is the fundamental law of both coexistence and succession in population genetics theory. Even the dynamic laws of the theory are usually used to assess the properties of the equilibrium states and steady state distributions. The Hardy–Weinberg law is a very simple, deterministic succession law that is used in a very simple state space. As parameters are added to the equation, we get different laws, technically speaking. For example, compare the laws used to calculate the frequency p' of the A allele in the next generation. Plugging only the selection coefficient against a recessive into the basic Hardy–Weinberg law, we get the recursion for the dominant allele frequency as $p' = p/(1-sq^2)$. Addition of parameters for the mutation rates yields a completely different law, $p'' = 1-\mu p' + \nu q'$, where μ is the rate of mutation away from the dominant allele, and ν is the rate of mutation toward it. We could consider these laws to be of a single type – variations on the basic Hardy–Weinberg law – which are usually used in a certain state space type. The actual state space used in each instance depends on the genetic characteristics of the natural system, and not usually on the parameters. For instance, the succession of a system at Hardy–Weinberg equilibrium, and of a system that is not at equilibrium but is under selection pressure, could both be modeled in the same state space, using different laws.

A theory can have either deterministic or statistical laws for its state transitions. Furthermore, the states themselves can be either statistical or nonstatistical. In population genetics models, gene frequencies that often appear in the set of state variables are statistical entities, thus the states themselves are also statistical entities. In general, a law is deterministic if, when all of the parameters and variables are specified, the succeeding states are uniquely determined. In population genetics, this means that the initial population and parameters are all that is needed to get an exact prediction of the new population state.

In sum, the structure of evolutionary theory can be understood by examining the families of models it presents. In the case of population genetics theory, the set of model types – stochastic and deterministic, single locus or multilocus – can be understood as related families of models. The question then becomes how to define the exact nature of the relationships among them, and how they relate to the rest of the evolutionary models, such as phenotypic or evolutionary-developmental models.

Expansions and Alternative Views of the Structure of Evolutionary Theory

In philosophy of science, the above analysis instantiates an approach to theory structure known as the 'semantic view,' that focuses on models (Giere, 1988; Suppe, 1977, 2000; Suppes, 1962; Van Fraassen, 1980). Some authors have misrepresented this approach, while others reject the semantic view yet support what they call a 'model-based' approach, whose differences from the semantic view are unclear (Downes, 1992; Godfrey Smith, 2006). For instance, Downes (1992: p. 143), Godfrey Smith (2006: p. 731), and Love (2012: p. 7) all claim that the semantic view is committed to 'mathematized theories,' which is not useful for some biological contexts. But both Beatty (1980) and Lloyd (1983) analyzed Darwin's (nonmathematical) selection theory and models as their first presentations of the semantic view of evolutionary theory. So clearly the semantic view can be used to analyze 'nonmathematized' theories and biological contexts. Especially in the hands of Suppes (1962), the semantic view can be used to analyze any structures into set theoretic terms, and thus into 'mathematical' terms (mathematics concerns structures, and all structures can be seen as mathematical objects); but the whole purpose is to represent the system in the most accurate, most useful, or most beneficial, etc., way. This does *not* mean that the analyzed structures are themselves represented mathematically *before* the analysis, and also does not mean that they are represented in equations *after* the analysis. Some authors also neglect the various hierarchies of evolutionary models offered using the semantic view, as outlined in Section The Structure of Darwinian Evolutionary Models, with misleading results (Godfrey Smith, 2006: pp. 732, 739ff; Lloyd, 1983: pp. 118–119).

In contrast, biologist Samuel Scheiner (2010) has recently offered an expanded account of the structure of evolutionary theory that takes the semantic view as its touchstone, and goes on to include other areas of biology. And Alan Love (2010) has provided a very interesting expansion of the analysis of evolutionary theory through the inclusion of developmental biology models and model types. The analysis of the structure of the theory offered in Section The Structure of Population Genetic Evolutionary Models for population genetics can thus be advanced and expanded, (using a variety of detailed methods of describing models, if needed), to incorporate developmental biology, by extending the linkages and overlaps of the model families understood to make up evolutionary theory. Love's overall approach is extremely useful, as it focuses on which research problems in evolutionary biology subfields compose the theory as a whole (2010, p. 428). Just as on the earlier analysis of Darwinian models in Section The Structure of Population Genetic Evolutionary Models, in Love's view, the entire hierarchy of models is explored, from the very abstract or general, to the extremely concrete. He emphasizes that different researchers use midlevel models in different ways and toward different ends; the resulting fully filled-out and concrete models can even be incompatible with one another. Love offers lists of model constraints from cellular and developmental biology that add additional model structure that may be needed to complement evolutionary models in order to fulfill the requirements of an extended evolutionary synthesis (Love, 2012: p. 8). By combining different empirical generalizations, some developmental biologists create mechanisms for the 'evolution of form' that can then be tested. (The component principles of these generalizations are not, themselves, best considered mechanistic models, according to Love (2012: p. 8)). The relevant causal mechanisms operate

on the level of individual ontogeny of organisms, not on population-level mechanisms such as natural selection or genetic drift. Thus we get the concrete level models just mentioned. Having a flexible and robust view of theory structure that can account for this wide range of models is imperative, for Love. He contrasts the complex and flexible view he derives from James Griesemer's (1984) semantic view account, with that of biologists Maxissimo Pigliucci and Gerd Muller (2010).

Pigliucci and Muller (2010) discuss the possibility of an extended evolutionary synthesis that is intended to incorporate evolutionary–developmental biology (evo–devo) in significant and integrated ways. They see the need for such an expansion as based on new concepts and findings in evo–devo that cannot be forced into their view of the traditional evolutionary synthesis from the 1930s and 1940s. Pigliucci and Muller offer an onion-type diagram to show the structure of evolutionary theory: they place 'Darwinism' as a circle at the very center of the onion, which includes only natural selection, inheritance, and variation. In the next outer ring, they place the 'modern synthesis,' which includes things like 'Mendelian inheritance,' 'speciation and trends,' population genetics, and gene mutation, etc. In the last, outer-most ring, which they call the 'extended evolutionary synthesis' Pigliucci and Muller place evo–devo theory, niche construction, multilevel selection, genomic phenomena, etc.

One apparent problem with this proposed structure is: how does evo–devo theory interact with natural selection, when they are layers apart in the onion? It seems that they have no integration, on this picture. Alan Love complains also that this model assumes a 'core' of evolutionary population genetics, which is always in operation, even though many have no wish to make such an assumption, and may explicitly reject it (Lloyd, 1988/1994: p. 8; Love, 2012: p. 6). The general problem with the onion picture is thus the lack of integration and relations among its parts, which is available under analyses that approach the structure as hierarchical and intertwined families of models, which include the detailed new evo–devo models.

A valuable alternative approach to the structure of current evolutionary biology as well as its history is presented by Telmo Piavani (2011), who offers a reconstruction inspired by philosopher Imre Lakatos. Piavani's updated Lakatosian approach dispenses with some weaknesses in the original Lakatosian approaches, including any strong falsificationism, and analyzes contemporary evolutionary theory into a flexible structure that delineates the theory's 'explanatory core' and its 'protective belt.' The traditional 'explanatory core' includes such concepts as: evolution as a fact, the tree of life, common descent, and natural and sexual selection. The explanatory core of evolutionary theory serves as the basic theoretical and assumptive background when building evolutionary explanations, and can be combined with other explanatory and theoretical tools from the 'protective belt,' which has expanded and contracted over time, depending on our state of biological knowledge. Currently, Piavani argues that the evolutionary core includes two hierarchies, one a genealogical hierarchy, namely of nested levels of transmission of genetic materials, organisms, demes, species, and monophyletic taxa. The other hierarchy is ecological, made up of, for example, organisms, populations like avatars, local ecosystems, and regional ecosystems, the key issue being the transfer of energy. Using these two hierarchies in the explanatory core, Piavani then describes a 'pluralistic protective belt,' that is, a set of models and assumptions, in addition to the 'explanatory core,' that may be appealed to by an evolutionary biologist when constructing an explanation (Piavani, 2011: pp. 12–13). This set of models and assumptions includes evo–devo. Piavani emphasizes that the theoretical changes that evolutionary theory has undergone since the modern synthesis in the 1930s and 1940s has been a progressive one, and now the theory is very healthy. The current dual core of the theory, and its various models and features of the protective belt demonstrate the growth of evolutionary knowledge since the modern synthesis (although they do have the disadvantage, according to someone like Love, of privileging some models as the 'core' of evolutionary theory.) Piavani also emphasizes that much of the theory is capable of 'falsification,' but *has not been falsified*, which concerns the testability and confirmation of the theory, the topic of section Confirming and Testing Models.

Confirming and Testing Models

In general, one evaluates a model by comparing the outcome of the model with empirical observations, and by independently testing the assumed conditions, including observations not available at the time of model construction (Lloyd, 1983: pp. 116–117). In population genetics, the most obvious way to support a claim of the form "this natural system is described by this model," is to demonstrate the simple matching of some part of the model with some part of the natural system being described. (Throughout this discussion, let us assume that each 'match' of model to a natural system in the real world involves a specification of the model, by filling in variable and parameter values, plus a determination from the real world of a 'data model' into a similar format. We will skip these specifications in our discussion, henceforth, and for simplicity, simply say that a "model matches or describes the natural world.") In a population genetics model, the solution of an equation might yield a single genotype frequency value. The genotype frequency is a state variable in the model. Given a certain set of input variables (e.g., the initial genotype frequency value, in this case), the output values of variables can be calculated using the rules or laws of the model. The output set of variables (i.e., the solution of the model equation given the input values of the variables) is the 'outcome' of the model. Determining the fit between model and natural system involves testing how well the genotype frequency trajectory calculated from the model (the outcome of the model) matches that measured in the relevant natural (or experimental) populations. It can be evaluated by determining the fit of one curve (the model trajectory or coexistence conditions) to another (taken from the natural system) using ordinary statistical techniques of evaluating curve fitting.

Also, numerous assumptions are made in the construction of any model, and testing a model sometimes involves confirming some or all of these assumptions independently. These include assumptions about which factors influence the changes in the

system, what the ranges for the parameters are, and what the mathematical form of the laws is. On the basis of these assumptions, the models take on certain features. Many of these assumptions thus have potential empirical content. That is, although they are assumptions made about certain mathematical entities and processes during the construction of the theoretical model, when empirical claims are then made about this model, the assumptions may have empirical significance. For instance, the assumption might be made during the construction of a model that the population is panmictic, that is, that all genotypes interbreed at random with each other. The model outcome, in this case, is still a genotype frequency trajectory, for which ordinary curve-fitting tests can be performed on the natural population to which the model is applied. But the model can have additional empirical significance, given the empirical claim that a natural system is a system of the kind described in the model. The assumption of panmixia, as a description of the population structure of the system under question, must be considered part of the system description that is being evaluated empirically. Evidence to the effect that certain genotypes in the population breed exclusively with each other (i.e., evidence that the population is not, in fact, panmictic) would undermine empirical claims about the model as a whole, other things being equal, and even if genotype frequencies (i.e., the model outcome) provide good instances of fit. In other words, the assumption that genotypes are randomly redistributed in each generation is intrinsic to many population genetics model types. Hence, although the assumption that the population is panmictic often is taken for granted in the actual definition of the model type – that is, in the law formula – it is interpreted empirically and plays an important role in determining the empirical adequacy of the claim.

By the same token, evidence that the assumptions of the model hold for the natural system being considered will increase the credibility of the claim that the model accurately describes the natural system. Technically, we can describe this situation as follows. From the point of view of empirical claims made about it, the model has three parts: state variables, empirically interpreted background assumptions, and those aspects and assumptions of the model that are not directly empirically interpreted. Because the possible outcomes of the model (along with the inputs) are actually values of the state variables, we can understand the input and outcome of the model as a sort of minimal empirical description of the natural system. If a model is claimed to describe accurately a natural system, at the very least, this means that the variables in which the natural system is described change according to the laws presented in the theoretical model. Under many circumstances, such models, in which only the state variables are empirically interpreted, are understood to be 'mere' calculating devices, because the match with the ('data model' extracted from the) natural system is so limited.

Various aspects of the model – for instance, the form of its laws, or the values of its parameters – rely on assumptions made during model construction that can be interpreted empirically. The assumption of panmixia, discussed above, is an empirically interpreted background assumption of many population genetics models. Because it is empirically interpreted, the presence or absence of panmixia in the natural population in question makes a difference to the empirical adequacy of the model. Finally, there may be aspects of the model that are not interpreted empirically at all. For instance, some parameters appearing in the laws might be theoretically determined and might have no counterpart in the natural system against which the model is compared.

Given that there can be aspects of the model structure that are not directly tested by examining the fit of the state variable curve, direct testing of these other aspects would give additional reason to accept (or reject) the model as a whole. In other words, it is taken that direct testing provides a stronger test than indirect testing, hence there is a higher degree of confirmation if the test is supported by empirical evidence. Direct empirical evidence for certain empirically interpreted aspects of the model that are not included in the state variables (and thus are confirmed only indirectly by goodness-of-fit tests), therefore provides additional support for the application of the model.

The above sort of testing of assumptions involves making sure that the empirical conditions for application of various parts of the model description actually do hold. In other words, in order to accept an explanation constructed by applying the model, the conditions for application must be verified. The specific values inserted as the parameters or fixed values of the model are another important aspect of empirical claims that can be tested. In some models, mutation rates, etc., appear in the equation – part of the task of confirming the application of the model involves making sure that the values inserted for the parameters are appropriate for the natural system being described. Finally, there is a more abstract form of independent support available, in which some general aspect of the model, for instance, the interrelation between the two variables, or the significance of a particular parameter or variable, can be supported through evidence outside the application of the model itself.

Lastly, variety of evidence, of which there are at least three kinds, is an important factor in the evaluation of empirical claims. I discuss three kinds of variety of evidence here: (1) variety of instances of fit; (2) variety of independently supported model assumptions; and (3) variety of types of support, which include fit and independent support of aspects of the model.

First, let us consider variety of fit, that is, variety of instances in which the model outcome matches the value obtained from the natural system. Traditionally, variety of evidence has meant variety of fit. There are two issues that must be distinguished when considering the variety of fit. One involves the range of application of a model or model type, while the other involves the degree of empirical support provided for a single application. Both of these issues involve the notion of independence, which needs to be clarified before continuing. One point of any claim to variety of evidence is to show that there is evidence for the hypothesis in question from different or independent sources. The notion of independence here is not the sort of independence that is found in the frequency interpretation of probability theory, where the independence depends only on accepting a particular reference class. Rather, in the context of scientific theories, independence is relative to whatever theories have already been accepted.

Significantly, in evolutionary theory, independence is usually relative to some assumption about natural kinds. Empirical claims are often made to the effect that a model is

applicable over a certain range of natural systems. Inherent in these claims is the assumption that all of the natural systems in the range participate in some key feature or features that make it possible and/or desirable to describe them all with the same model type. Thus, there is some assumption of a natural kind (characterized by the key feature or features) whenever a range of applications arises. The scientist, in making a claim that the model type is applicable to such and such systems, is making an empirical assumption about the existence of the key feature or features in the range of natural systems under question. Hence, for evolutionary models, testing for variety of fit depends on accepting an assumption about what constitutes different or independent instances of fit; this, in turn, amounts to accepting a particular view of natural kinds. Part of what variety of evidence does, in a bootstrapping effect, is to confirm this original assumption about natural kinds. More technically, variety of evidence confirms the sufficiency of the parameters and state space.

Take the case in which a model type is claimed to be applicable over a more extended range than that actually covered by available evidence. This extrapolation of the range of a model can be performed by simply accepting or assuming the applicability of the model to the entire range in question. A more convincing way to extend applicability is to offer evidence of fit between the model and the data in the new part of the range. Provision of a variety of fit can thus provide additional reason for accepting the empirical claim regarding the range of applicability of the model.

For instance, a theory confirmed by 10 instances of fit involving populations of size 1000 (where population size is a relevant parameter) is in a different situation with regard to confirmation than a theory confirmed by one instance of each of 10 different population sizes ranging from 1 to 1 000 000. If the empirical claims made about these two models asserted the same broad range of applicability, the latter model is confirmed by a greater variety of instances of fit. That is, the empirical claim about the latter model is better confirmed, through successful application (fits) over a larger section of the relevant range than the first model. Variety of fit can therefore provide additional reason for accepting an empirical claim about the range of applicability of a model. Variety of fit can also provide additional reason for accepting a particular empirical claim, that is, one of the form, "this natural system is accurately described by that model." That is, variety of evidence can serve to increase confidence in the accuracy of any particular description of a natural system by a model.

Variety of fit is only one kind of variety of evidence. An increase in the number and kind of assumptions tested independently, that is, greater variety of assumptions tested, would also provide additional reason for accepting an empirical claim about a model. The final sort of variety of evidence involves the mixture of instances of fit and instances of independently tested aspects of the model. In this case, the variety of types of evidence offered for an empirical claim about a model is an aspect of confirmation.

According to the view of confirmation sketched above, claims about evolutionary models may be confirmed in three different ways: (1) through fit of the outcome of the model to a natural system; (2) through independent testing of assumptions of the model, including parameters and parameter ranges; and (3) through a range of instances of fit over a variety of the natural systems to be accounted for by the model, through a variety of assumptions tested, and including both instances of fit and some independent support for aspects of the evolutionary model.

Exchange in Anthropology

Abstract

Anthropological research into exchange stretches back to the origins of the discipline. In surveying the history and findings of this research, it is shown that anthropology's qualitative method of studying exchange can be seen as complementary to, rather than in competition with, the quantitative study of exchange within the discipline of economics. In the late 1980s, the study of exchange within anthropology turned upon several important texts that have helped to set the agenda leading up to the current day.

Introduction

In some ways, the study of exchange within anthropology still hews very closely to Malinowski's early attack against the "current economic text books" (Malinowski, 1961: p. 46). In those pages, he complained that the discipline of economics had proclaimed that "primitive man" was merely "actuated by pure economic motives of enlightened self-interest." Malinowski, on the other hand, was at pains to show that the Trobrianders of his own research were instead prompted to action by motives that were "highly complex, [and] not directed towards… the direct achievement of utilitarian purposes" (Malinowski, 1961: p. 46). Indeed, it could be argued that it is hard to grasp anthropological exchange theory without grasping its long battle with the discipline of economics. Despite occasional harmonic interludes, both disciplines produced and reproduced two influential, but separate, lines of inquiry that divided the world of exchange theory into qualitative and quantitative approaches.

In engaging this now age-old battle, the anthropological study of exchange built up a large, twentieth-century edifice upon the supposed distinction between 'nonmarket' and 'market' exchange. Once anthropology's bailiwick was circumscribed and fortified, the discipline became the suitable zone of expertise on all matters relating to the 'gift economy,' a space wherein one could find unquantifiable and nonutilitarian values circulating, such as love and communal commitment. Economics, meanwhile, focused on the market-based circulation of commodities, governed by the quantifiable value of money (see Hann and Hart, 2011: pp. 12–13).

But for at least 30 years, anthropological research has questioned why its theories of exchange must be cordoned off within the gift economy or the nonmarket sphere. Gifts and commodities are no longer so easily segregated from one another, nor is quantity from quality. Rather, much research has focused on how quantitative value assessments and exchanges are socially produced in the first place. Equally, one might say that Benjamin's (1999: p. 18, passim) belief in the quasi-mystical 'phantasmagoria' of commodities has become at least as vital to advances in the anthropological study of exchange as Mauss's enduring notion of the 'hau' of the gift. (To be fair, Mauss spoke of similar issues in his conclusion, when he wrote, "Things sold still have a soul" (1990: p. 66). But the more general neglect of these comments is symptomatic of the enduring divide described here.) This article, therefore, will first chart the developments that emerged out of the bifurcation between the qualitative and the quantitative, and then conclude by showing new trends within the anthropological study of exchange that have begun to productively breach these strongholds.

The Concept of Exchange

The old Rousseauian-Marxist concept of 'alienation' proves to be foundational when searching for an overarching rubric for generations of anthropological exchange theory. Both classical anthropological theory as well as more recent work relies on the idea that the only things that can be exchanged are things that can become detached from individuals or societies, even if there is disagreement about what, precisely, becomes detached (see below for an important challenge to this general paradigm). One exchange partner has an item of value that he or she can do without, while another seeks to obtain this precise item in exchange for something that this second exchange partner is equally willing to alienate. For this reason, classic anthropological studies diagram exchanges as shown by Gregory (2001: p. 5039), "where A gives B the object x in exchange for the object y":

$$A \underset{y}{\overset{x}{\rightleftarrows}} B$$

While this may state the obvious, alienation is intriguing as a starting point for at least two reasons. First, it illuminates culturally produced visions of self and other – along a wide spectrum from the individual to the family to the national level. A classic example emerges out of the Ricardian (1821) understanding of comparative advantage. A country in a northerly clime might decide that it could, indeed, grow grapes at all costs, by investing in heavy infrastructure such as greenhouses and energy. If it were to do so, it would be collectively deciding that it was unwilling to exchange anything for grapes; that is, it would be refusing to alienate the capacity to grow grapes to an Other outside of itself, for it

views the growing of grapes as constitutive of its own self-perception and internal needs. This vital item, therefore, cannot be cast into the more dangerous and tenuous field of exchange, but must remain self-produced and unalienated. A less frivolous example of this would be a country that insisted on retaining its capacity to produce military materiel, for fear that leaving this to the realm of exchange could leave it highly vulnerable. In this sense, exchange constantly affirms, reaffirms, and challenges the borders of self and other.

Second, the grounding concept of alienation is fruitful for it frames another crucial issue with regard to exchange: property. Exchange sets in motion an entire field of variant property relations – socially legitimated ways in which objects can be attached, detached, and reattached to different bodies, whether individual or corporate. Some of the most important contributions from anthropology have evolved out of its long-standing insistence that property itself can be a field of contestation or misunderstanding. This greatly complicates a more utilitarian approach to exchange, which typically can only envision fee simple and freehold ownership structures (so much so that the technical term 'usufruct' has largely disappeared from English vernacular). Anthropological studies of cooperatives, commonly held land, inalienable goods, and other such modes of property and nonproperty serve as reminders that the notion of property can come in many shapes and sizes. Since the 2008 financial crisis, when the general public learned that hedge funds have the capacity to sell assets that they do not even own, it has become increasingly clear that anthropological approaches to exchange can easily expand well beyond their old boundaries in 'native life.'

Both these foundational concepts – alienation and property relations – allow other vital aspects of social life to come to the fore when analyzing exchange, whether one is talking about the inversion of exchange (i.e., hoarding), the division of labor, the interplay between hierarchy and equality, the relationship between power and redistribution, and, finally, the role of value itself in the grounding of social life. Considering this, one can quickly see why a reduction of exchange to mere utilitarian price fails to explain the rich and complex panoply of issues that grow out of it.

Examples from the Corpus

A review of the primary advances in the theory of exchange within anthropology will quickly confirm the discipline's commitment to this nonreductionist, qualitative approach. Beginning with Boas (1966: pp. 77–104), who first studied the famous potlatch ceremony, one sees a drive toward studying exchange from a nonmaterialist perspective. How, he wondered, could people actively seek to extinguish wealth, rather than cultivate it? The Smithian (1976 [1776]) notion that exchange and the expansion of material prosperity went hand-in-hand seemed turned on its head by studies such as these.

Malinowski picked up this thread, by attempting to provide an extensive typology of exchange, ranging from "pure gifts" (characterized by the socially binding exchanges displayed within family life) all the way to "trade, pure and simple," which was governed by "mutual advantage" (Malinowski, 1961: pp. 177–191). He argued that, by way of placing any given exchange of values somewhere along this spectrum, the Trobrianders navigated and built the wide variety of social ties present in their day-to-day lives. Further, each type of trade was accompanied by a corresponding type of social behavior. For example, crude haggling prevailed during "trade, pure and simple," but highly specific religious taboos governed certain customary payments (Malinowski, 1961: pp. 332–333).

If Malinowski focused on the shifting role of humans in any given exchange, Mauss interceded in the debate by making the profound suggestion that objects themselves might also carry peculiar powers that help to motivate and circumscribe exchange: "Souls are mixed with things; things with souls…. Each emerges from their own sphere and mixes together. This is precisely what contract and exchange are" (Mauss, 1990: p. 20). Most famously, he picked up a Maori term – 'hau' – that has become rote knowledge for all anthropologists since. The 'hau' of an object represents a certain spirit of the original giver that has moved into the object itself. In particular, the 'hau' sets in motion the spirit of reciprocity and obligation, because this 'hau' is a spiritual element hearkening from the object's place of origin, to which it always seeks to return (Mauss, 1990: pp. 8–13).

Levi-Strauss swept into anthropological exchange theory with revelatory fervor, born out of a belief that structural linguistics could provide newfound objectivism to a discipline dominated by subjectivism. In *The Elementary Structures of Kinship* (1969), Levi-Strauss attributes a material value to women, thereby mobilizing them into the sphere of exchange. In his theory, they are but the supreme commodities (a "group's most important assets," p. 479), to be transferred among and across generations of men. The incest rule, in this telling, is much like a gold standard; because it proscribes access to a specific range of women in any given kinship system, Levi-Strauss sees it is a purely artificial method for ensuring that the availability of women is never allowed to inflate away in a sea of endless abundance. And yet, despite this reductionist approach, Levi-Strauss still follows Durkheim's dictum that the sphere of exchange had a meaning well beyond the mere satisfaction of material needs and wants. For him, exchange "provides the means of binding men together, and of superimposing upon the natural links of kinship the henceforth artificial links… of alliance" (Levi-Strauss, 1969: p. 480). Important critiques of his theory, influenced by feminist anthropology, can be found in Rubin (1975) and MacCormack and Strathern (1980).

Bourdieu's giant corpus (e.g., 1987 and 1991) can be seen as related to Levi-Strauss's, in that he also imports the quantitative spirit of economic theory into anthropological theory. While many critics of economics have adopted Bourdieu's insistence that there are many types of capital beyond the mere economic form, ultimately, his conceptual apparatus assumes that these multiple forms of capital will seek out self-maximizing returns. He qualifies capital by farming it out to a host of different types, but each is nevertheless actuated by the same 'enlightened self-interest' that Malinowski deemed to have insufficient explanatory power. Issues posed by ethnographic evidence such as the potlatch would pose no trouble for Bourdieu: the destruction of economic capital would merely be a mode of investing in symbolic capital.

On the heels of Levi-Strauss's open embrace of economic reductionism, anthropological exchange theory delved into its infamous 'formalist/substantivist debate,' wherein the discipline officially segregated itself by way of the quantitative and qualitative divide. The substantivists insisted upon a non-reductionist approach, and gradually came to dominate what is today known as cultural anthropology, while only a small group of formalist anthropologists continued to follow developments in the field of economics in order to see if these theories could be applied to their own field sites (but see Geertz, 1978). Bohannan's article on *"The impact of money on an African subsistence economy"* (1959) still stands today as a centrally influential piece in solidifying the substantivist approach. In it, he follows Polanyi's radical claim (1957) that, contrary to popular beliefs, money can be enshrouded in qualitative distinctions, thereby generating a diverse range of quantitative measuring sticks. Using the Tiv of West Africa as his example, Bohannan argues that the circulation of valuables can be circumscribed by a set of complex social rules, each with its own 'sphere of exchange' dominated by its own 'special purpose money.' However, as 'modern,' 'general purpose money' arrives, it reveals a stunning capacity to traverse these rules, thereby causing all the previously segregated qualities of the different valuables to only be assessed now on a single numeric scale. Hann and Hart (2011) have recently revisited the power of Polanyi's approach to markets and exchange, and argue for some of its insights to return to debate.

Sahlins also had an enduring impact on anthropological exchange theory with his book *Stone Age Economics* (1972). Several chapters have had broad influence, but in particular, the two final chapters stand as benchmarks. In the final chapter, Sahlins compellingly maps the role of social relations onto supply and demand, thereby insisting that "Lacking a trade contact, a man may not be able to get what he wants at any price" (1972: p. 298). From this vantage point, supply and demand take a distinct backseat to the power of social relations, and price is far from being the only variable that can determine whether a market clears. In the penultimate chapter, Sahlins builds upon Malinowski's claims, in order to reveal that his old typology of exchange correlates with kinship distance. In short, "the span of social distance between those who exchange conditions the mode of exchange" (p. 196). In this enhancement of the model, one comes to see that theft is practiced exclusively upon extreme outsiders, while near kinsmen would show "voluntary food-sharing," and "the expectation of a direct material return is unseemly" (p. 194).

Hart contributed to this vision by expanding into the distinctions between barter and ceremonial exchange, arguing that "one form [ceremonial exchange] is a temporary social framework erected in the relative absence of society; the other [barter] is an atomized interaction predicated on the presence of society" (1986: p. 648). Equally, Parry and Bloch's collected volume, *Money and the Morality of Exchange* (1989), added a temporal dimension to Sahlins' spatial one: in it, they announce that research findings from diverse locales suggest that many societies perceive two distinct modalities of exchange: those that are dictated by short-term and long-term time horizons. The former tend to be viewed as more individualistic and materialistic, while the latter tend to be seen as more selfless and community spirited. Despite the impact of this tradition that maps social distance onto types of exchange, Zelizer's important research, *The Social Meaning of Money* (1997), complicates much of this. In her study of the earmarking of money within the American household, she finds that even nuclear family members can sometimes treat each other as callous exchange partners, or as potential targets of thievery.

In his book *Gifts and Commodities* (1982), Gregory represents the high-water mark of the twentieth-century tendency to separate the world into market- and nonmarket-based exchanges; in it, he succinctly proposes a dichotomous definition for gifts and commodities: the former stand as "*inalienable* objects transacted by non-aliens," while the latter represented "*alienable* objects transacted by aliens" (1982: p. 43, emphasis in original). However, if his 1982 book was unfairly misunderstood by its critics, his later contribution, *Savage Money: The Anthropology and Politics of Commodity Exchange* (1997), has been broadly influential to students of anthropological exchange theory. In it, he deftly blends the tradition of political economy from Smith to Marx to Sraffa with the anthropological study of exchange from Malinowski to Levi-Strauss to Sahlins. One chapter productively re-imagines the ubiquitous 'quantity theory of money' as a 'quality theory of money,' while yet another forces the reader to question a centuries-old and well-nourished hatred of the village usurer. This latter work put to use the best of the anthropological tradition, by bringing ground-level ethnographic detail to an age-old problem. In so doing, Gregory explodes influential theories that have greatly impacted many people's lives, as they have been adopted by powerful institutions such as The World Bank.

New Directions

If the formalist/substantivist divide can be read as one that insisted upon a stark categorical divide between quantity and quality, then one might say that the last 30 years have evidenced the slow unraveling of these borders. Perhaps inspired by a Deleuzean postmodernist spirit, or perhaps by the influence of the transnational moment, anthropological exchange theory no longer dwells too much upon this divide. Instead, it has tried to move into new productive spaces – often the spaces that open up as a result of seeing the various transgressions across the quality/quantity border. These new spaces do not so much dismiss the vitality and significance of this divide, as much as they seek to find alternative pathways to different insights, since the insights from the quantity/quality divide are now well rehearsed, and in significant measure, well accepted.

In retrospect, one can see that a thicket of arguments published in the late 1980s and early 1990s set the stage for this new movement. Appadurai's much-cited chapter in his edited volume by the same name, *The Social Life of Things*, liberated a generation of scholars who had been weaned on the quantity/quality divide. Equally, it helped spur scholars to push anthropology well past the 'traditional' societies that had been its standard bailiwick, suggesting that

anthropological method and its theories of exchange could be applied fruitfully to the circulation of commodities in 'modern' societies as well. Moreover, Appadurai insisted that one not fetishize the gift economies of traditional society to the exclusion of noticing the proliferation of commodities in their midst (as Gregory had also probed). Commodities are not the special preserve of capitalism, he says. In other words, his long essay can be seen, not least, as an effort to fight against an anthropology that was "excessively dualistic" (Appadurai, 1986: p. 12). Instead, he turned to examples such as the kula to argue against the twentieth-century paradigm, explaining that there is a "difficulty in separating gift and commodity exchange even in preindustrial, nonmonetary systems, and it reminds us of the dangers in correlating zones of social intimacy too rigidly with distinct forms of exchange" (Appadurai, 1986: p. 22).

An array of scholars interested in the application of exchange theory well outside the bounds of the 'gift economy' has been highly influenced by Munn's (1986) *The Fame of Gawa* (not least, Appadurai, whose text hinges on her arguments). Munn brilliantly altered the focus of inquiry concerning exchange by demanding to know the meaning of 'value' itself, and how it is constituted and sustained, rather than assuming it as a given. Consequently, this text, especially when read in its entirety, provides a supple and nuanced incursion into decades of literature on exchange. Munn argues that 'value' is nothing more, nothing less, than the ability of subjects to move through space and time. The successful deployment of value thereby reinforces spatial and temporal pathways through which others can move as well. Contrariwise, the destruction of value causes the shrinkage of these same intersubjective pathways. Seen from this light, 'value' is a sort of metaphysical potency that cannot be denominated, but can nevertheless be studied as part of the vital effort on the part of subjects as they both cooperate and compete in order to build viable communities. A community without value devolves into atomism, just as a community that robustly allows for the increase in value will be gain in strength.

Strathern's (1988) *Gender of the Gift* likewise transformed questions concerning exchange by shining light upon the Western underpinnings of exchange theory itself: "I choose to show the contextualized nature of indigenous constructs by exposing the contextualized nature of analytical ones. This requires that the analytical constructs themselves be located in the society that produced them" (1988: p. 8). Most radically, Strathern questioned something at the very heart of a century of exchange theory – the supposed antinomy between society and individual. To do so, she reintroduced a term from Marriott (1976), 'dividual,' in order to point out that our own belief that a person is a bounded and pure 'individual' that can be circumscribed from other individuals is a Western social construct, not a universal truth about human life per se. Strathern then goes on to insist upon the concept of 'mediated' versus 'unmediated' exchanges, in order to discuss Melanesian notions of personhood that often rest upon circulating objects that are seen as 'partible' aspects of the giver. The object, therefore, does not carry a 'hau' as in the old Maussian argument, but rather, the valued object or substance is viewed *as an actual part* of the giver himself or herself. As Strathern makes clear, this proposal greatly undermines the common belief that alienation of persons and objects serves as a pillar of exchange itself, as described above. Objects are, instead, also subjects that help forge the actual personhood of givers and receivers as exchange continues apace.

Weiner (1992) intervened powerfully in exchange theory at this time as well, by building upon its long-standing neglect of 'inalienable possessions,' that is, the valued objects that are held in reserve and only rarely step out into the world of trade. She claimed that the mundane exchange of replicable and alienable goods only occurs as part of a competition (or, in Appadurai's terms, a "tournament of values") that is organized around the disputed ownership of one unique, inalienable good. Thus, exchange partners ranged in a hierarchy are all battling each other in order to wrest away control of an inalienable good hoarded by their more powerful trade partner. 'Inalienability' is only a relative concept here, since she readily admits that often these inalienable goods (e.g., family heirlooms) are only less *likely* to move into the sphere of exchange, rather than that they will never do so. In this sense, Weiner's text is intriguing for its unintentional, but harmonic, convergence with a long range of thought from economics with regard to fractional reserve banking, Gresham's law, and hoarding. Thus, with Weiner, one can see that anthropology is perhaps trending back toward the economic theory that it had banished back with the discipline's original emergence. Perhaps this is not so surprising, since Weiner herself insists that "It is imperative that we sever what is left of the Enlightenment's partition of humanity into two camps – the 'primitive' and the West. To achieve this goal we must recognize that creating inalienable possessions is a human endeavor, universally practiced, and that local manifestations, as diverse as they are, can be compared" (1992: p. 155).

At least some of Guyer's many contributions can be viewed in light of this trend as well. While still critical of much of economics literature, she still represents the beginning of a promising trend that envisions a more robust conversation with economics. Although her method is rigorously ethnographic and she resolutely refuses to import any reductive modeling, her analysis is influenced by ideas from within economics that anthropological theorists have often tried to dismiss in the past. For example, she embraces the idea that many social actors can be governed by the seeking of profit via 'instrumental calculation,' although she believes that it blossoms into something far more variable and complex than standard economic models would allow (Guyer, 2004: pp. 17–18, 25). She has also productively intervened in the age-old discussion concerning spheres of exchange (see above), by focusing on 'asymmetric exchange.' Even though much writing on exchange since Adam Smith has assumed that exchange only occurs when items of equal value are traded, Guyer probes exchanges where the goods traded are of manifestly unequal values. With this focus, the constitution of socially mediated space and time, and what economists refer to as 'path dependency,' comes more to the fore. To wit, "without questioning Bohannon's ethnography at all," Guyer can reinterpret the spheres of exchange argument by mapping it onto a network of spatially organized and hierarchical trade

networks (2004: p. 28). What initially appears as a localized moral coding involving the purity of various spheres can now be seen, instead, as the asymmetric flow of different objects of value across different political–economic spaces.

Similar to Guyer's reminder concerning asymmetrical exchanges, Roitman's study of exchange practices in the Chad Basin, entitled *Fiscal Disobedience* (2005), has provoked a new look at some age-old categories from within the literature. First, Roitman studies the shifting moral valences of debt, thereby complicating old folk – and analytic – beliefs about the moral and economic dangers of it. Likewise, she has challenged a central feature of much study of exchange in anthropology – the purported divide between formal and informal sectors of the economy. First coined by Hart (1973), the formal/informal divide relies on the idea that the state is involved only in the formal market, whereas the informal market is somehow 'outside' the state's gaze and management. Instead, much in keeping with the Deleuzean trends of recent years, Roitman sees this binary opposition as a zone of fruitful transgression rather than a clear-cut and obvious ideal type, and she reveals how the state plays a significant role in the informal sector, despite its supposed neglect. In so doing, she finds evidence that even the seemingly 'unregulated' layers of exchange are, indeed, regulated, but merely by a widely contested field of social actors.

Further breakdowns of straightforward binarisms such as quantity/quality, credit/debt, state/market, subject/object, real/artificial, gift/commodity, and market/nonmarket are characteristic of current thinking in anthropological exchange theory. Increasingly, anthropologists are studying the social constitution of such binarisms rather than presuming them as given; equally, they are confronting the many zones in which these supposedly stable categories bleed in and out of one another (intriguingly, these advances can also be seen in economics, in such developments as Behavioral Economics). Zaloom (2006), for example, finds that the most emphatically market-oriented zone – the Chicago Board of Trade – is riddled with social relationships. With fine-tuned attention to such things as the quantitative movements of the yield curve, Zaloom instead studies the way in which quantity and quality work together, rather than stand apart, in everyday exchange. Chu (2010), meanwhile, reminds us that people might even see exchange transactions as transcending death itself, as people seek out sacrificial exchanges with their ancestors. Shipton also pivots upon this issue, and his recent trilogy (2007, 2009, 2010) provides an excellent example of how exchange theory can provide new insights while still retaining a foundational interest in the discipline's original questions concerning alienation and property.

Maurer has boldly followed the tendency to transcend these binarisms until one witnesses their complete unraveling. By combining analyses of three institutions that might ordinarily be studied separately – offshore finance, Islamic finance, and the local currency movement – Maurer argues that the traditional focus that saw exchange theory grounded in the notion of 'adequation' needs to be redirected. Adequation relies upon Saussure's axiomatic belief in a harmonic overlap between sign and object; as such, it lays the groundwork for the idea that objects' value can be compared and made equivalent by way of a clear, quantitative sense of price. But just as the poststructural critique undermines this axiom within linguistics itself, so too does Maurer believe that exchange theory needs to move away from it. One can do so, he shows, by studying exchanges wherein adequation has failed – much like when Guyer insists upon studying asymmetric exchanges – and people continue to exchange despite their acknowledgment that there is no trade of equivalents. Indeed, he labels the concept of equivalence itself as "part of the fantasy work of fetishism" (Maurer, 2005: p. 112), just as he dismisses the search for a theory of value as an old modernist proclivity that should be abandoned (Maurer, 2005: pp. 21–22). If one can say, then, that much of anthropological exchange theory was built upon Saussure's axiom, then Maurer's work to integrate more recent interventions in linguistics by the likes of Deleuze, Derrida, and Zizek could mark a new turning point in how anthropology assesses exchange.

Conclusion

In spite of some of these recent movements toward more cross-fertilization, anthropology's ongoing debates with economics will hopefully never cease, since such contention can be extraordinarily productive for all parties. For example, Graeber (2010) has recently taken economics to task for its centuries-old failure to account for the vast empirical record regarding the origin of money in credit, rather than barter. Another exciting development born out of this tension is the welter of research emerging out of the Institute for Money, Technology and Financial Inclusion (IMTFI) (see Schwittay, 2011). By relying on the qualitative ethnographic method, researchers at this institute have reframed a highly consequential debate about the global poor's lack of access to financial services. Instead of assuming that change comes from researchers, think tanks, or corporations, IMTFI assumes that the end users of the financial services can themselves be the financial innovators, inventing and utilizing new forms of money and accounting that emerge from grassroots practice. But no matter the topic of study, the enormous changes in the world economy in the past 10 years ensure that anthropological practice and theory will continue to evolve well into the future, working off of the recent advances described here.

Abstract

Social exchange theory is one of the major theories of social interaction in the social sciences. Homans, Blau, and Emerson were the key theorists who developed the original theories of social exchange. Theoretical and empirical developments include the extension of their work to the analysis of power and dependence, social networks, reciprocity, fairness, social cohesion, and solidarity. The work on social exchange in sociology has clear links to research on social capital, particularly work on networks, norms, and trust. Contributors to this tradition of research include Cook, Friedkin, Lawler, Molm, Willer, Yamagishi, and their collaborators.

Social exchange theory is one of the primary orientations to the analysis of social interaction and social structure. Social relations are viewed in terms of the primacy of the costs and benefits exchanged in interaction. Social structures are viewed as networks of connected social relations between individuals or groups, sometimes acting through agents. The behavioral basis of the theory varies depending on the specific theorist. Homans based his original formulation on the behaviorist tradition, as did Molm in her early work. Homans examined the reinforcement principles that play out in the behavior of actors in interaction with one another. Blau eschewed behaviorism and based his original formulation on cognitive concepts from psychology and microeconomics: preferences, interests, indifference curves, supply, and demand. Subsequent formulations, including the work of Emerson and Cook, tended to blend aspects of these two foundations. Initially a major focus of exchange theory was the study of power and its structural bases. The power-dependence perspective first developed by Emerson to apply to dyads was later extended to apply to the study of exchange networks. In Emerson's (1972) work coalitions, division of labor, specialization, and related processes were analyzed in terms of power dynamics (e.g., Cook and Gillmore, 1984). Some of the major developments in exchange theory include the analysis of power, networks of exchange relations, and processes of structural change and applications of these principles. More recent developments include the study of commitment, trust, and solidarity.

Social exchange theory has its origins in the field of sociology in the work of George C. Homans and Peter Blau. Homans' (1958) famous paper entitled 'Social Behavior as Exchange' laid the foundation of this orientation to the study of behavior. He subsequently expanded these ideas in *Social Behavior: Its Elementary Forms*, published in 1961 (1974). The primary focus of his work is what he referred to as 'subinstitutional' or elementary behavior, the actions of individuals in direct interaction with one another that form the bedrock of groups and organizations. He contrasted elementary behavior with institutionalized forms of behavior, such as that involved in conforming to norms or to role prescriptions for appropriate behavior. For Homans, institutionalized behavior and elementary forms of behavior were most often distinct. He argued that elementary behavior could sometimes 'crack the institutional crust,' forcing changes in the institutionalized ways of doing things (e.g., the changes in social behavior and institutions forged by rebellions and revolutions). This orientation set his work apart from some of the dominant thinking at the time, particularly the work of Parsons.

Major Theoretical Formulations: Blau and Homans

Blau (1964), in his famous book, *Exchange and Power in Social Life*, developed a much more extensive treatment of the links between microlevel social behavior and the groups, organizations, and institutions it constitutes. A major difference between the perspectives of Homans and Blau is the latter's recognition of 'emergent' processes at more complex levels of social organization. For Blau, the whole is more than the sum of its parts. Relationships between the parts or elements of the structure create emergent processes that evolve from the interaction of the parts, but are not reducible to properties of the individual elements. Homans, in contrast, adopted a reductionist orientation to explanation using exchange principles arguing that many of the 'laws' of social organization could be understood in terms of the behavior of the interacting parts, typically individuals. For this reason, according to Homans, psychological principles ultimately laid the foundation for the laws of elementary social behavior.

While Homans' efforts were aimed at understanding elementary behavior, Blau's aim was much more macro in focus. He intended to formulate a theory of social structure and institutions based on a sound microfoundation. He presented his book on social exchange as a 'prolog' to a theory of social structure. The origin of Blau's vision of social behavior was not behaviorism, as in Homans' case; rather, it was a more sociological version of microeconomics, which he labeled 'social exchange theory,' borrowing the term from Homans. (For a lengthy critique of Blau's use of microeconomic reasoning see Heath, 1976, among others.) In many ways, Blau's work was one of the first major theoretical efforts to extend the logic of microeconomics to the analysis of social behavior, a task that much later won Gary Becker the Nobel Prize in Economics. Homans instead based his analysis of the social behavior he called 'exchange' on principles of behavioral analysis derived

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32056-6

from the work of the behaviorists famous at the time he wrote. A major influence on his theoretical work was the empirical research of B.F. Skinner, his well-known colleague at Harvard.

Both Homans and Blau addressed indirect exchange processes, though such processes form a much more significant component of Blau's theoretical formulation. Homans acknowledged the importance of the indirect ties that actors have when they are in direct exchange with the same sets of individuals. For example, employees of the same employer have indirect exchange relations with each other through their direct contacts with their employer. Blau extended the analysis of indirect exchange, acknowledging the role it plays in larger and more complex collectivities as well as in collective action. In particular, Blau viewed indirect exchange as the basis for coordinated action in complex social structures (and the substructures of which they are composed). This coordination of action through indirect exchange in larger collectivities necessitates mediation by common values, which can be the focus of opposition and conflict, especially as the social structures involved become more complex. Blau discussed group formation, cohesion, integration, differentiation, opposition, conflict, and dissolution as significant forces of structural change and stability in complex social structures. These forces played a major role in his theory of social exchange as he endeavored to provide a comprehensive microfoundation for macrosociology. Homans and Blau were both engaged in distinctive efforts to produce a coherent theoretical alternative to Parsonian functionalism, the dominant paradigm in sociology until the late l960s.

The Roots of Social Exchange Theory

Somewhat independently, Homans and Blau developed their theories of social exchange even though each had been well versed in functionalism and Parsons' social systems approach to the analysis of society. The vestiges of both traditions are clearly evident in Blau's treatment of social exchange, though much less so in the work of Homans who labored skillfully to ground his theory of exchange explicitly on Skinnerian principles of behavioral analysis, repudiating the need for more macro-level concepts and principles. Blau's goal was to produce a theory of social structure by clarifying the nature of the social processes and associations that generate the more complex structures of organizations, communities, and societies. He explicitly attempted to link the sociology of everyday life popularized in the work of Simmel and Goffman with the broad theories of society characteristic of Weber and Parsons. Unlike Homans, however, his focus on the interpersonal was primarily as the basis for theorizing about more complex forms of association.

Psychological Roots

Besides functionalism and Parsons' version of systems theory other influences on the development of social exchange theory came from an eclectic set of sources including pragmatism, utilitarianism, behaviorism (for Homans), and conflict theory (in the case of Blau's work). Turner (1986) provides a fairly accurate and detailed account of the various roots of social exchange theory in his discussion of the development of this theoretical orientation and its impact in the field of sociology. In addition to these sources of influence, the major works of several psychologists and anthropologists provided further impetus to the development of the exchange paradigm in sociology. The dominant contribution from psychology is the work of John Thibaut and Harold Kelley (1959), *The Social Psychology of Groups*. This volume presents a lengthy treatment of the forms of interdependence among individuals engaged in various types of social interaction. In matrix format it lays out the rewards and costs attached to different behaviors under varying conditions of interdependence. The framework is used to make predictions about behavior given different types of control over the outcomes of the other actor(s) in the situation. For example, Thibaut and Kelley (1959) distinguish behavior control from fate control in social relationships using their basic orientation to interdependence. Their work formed the basis of much experimental research in psychology over the next several decades primarily on cooperation, competition, negotiation, and coalition formation. It also dovetailed nicely at that time with the emergence of game theory in the social sciences as a tool for understanding strategic interactions, particularly in psychology, economics, and political science.

Anthropological Roots

The early work of anthropologists like Levi-Strauss (1969 [1922]), Malinowski (1922), and Mauss (1925) influenced exchange theory in an entirely different way. Sociologists drew upon the fieldwork of these scholars to provide examples of the significance of social exchange, often contrasted directly with economic exchange. Malinowski (1922), for example, in his comprehensive analysis of the Kula Ring among the Trobriand Islanders, argued that the exchange of arm bands for necklaces across the islands over time was an important source of social solidarity, the significance of which far exceeded the economic value of the items exchanged. Blau (1964), and subsequently Richard Emerson (1972, 1981), developed conceptions of indirect exchange and generalized exchange based to some extent on Malinowski's extensive fieldwork. Mauss's (1925) complex analysis of the gift also provided input to the development of theory concerning generalized exchange and reciprocity (see Molm, 1997; Molm et al., 1999 on reciprocal or non-negotiated exchange; Yamagishi and Cook, 1993; Bearman, 1997; Molm et al., 2007 on generalized exchange).

Exchange Theory: Empirical Research

Homans and Blau popularized exchange theorizing in sociology in the late 1960s and early 1970s, but sustained empirical research on the topic did not begin until the mid-1970s largely as a result of the influence of Emerson's (1972) more formal theoretical work, based on his earlier treatment of power-dependence relations (1962, 1964). Ironically, Emerson's work on power-dependence relations also influenced Blau's (1964) discussions of power and power-gaining strategies. Emerson built a conception of social exchange around his fundamental insights concerning

power in social relations. He, like Blau, made power and inequality central to his treatment of exchange processes. Similarly, like Blau, he viewed his theory of social exchange as the beginning steps toward formulating a general theory of social structure. In Emerson's case, however, the structures of primary interest were the networks formed as a result of the connections among a set of actors engaged in social exchange with one another. Two of Emerson's distinct contributions to exchange theory in sociology are his fundamental insight into the relational nature of power and his extension of exchange theory to analyze the social networks created by exchange relations.

Before expanding on these two major contributions to the development of exchange theory it is worth noting that Emerson's first efforts to formulate a theory of social exchange had more in common with Homans's work than that of Blau, despite their common goal of building a theory of social structure. In the two papers written in 1967 (and subsequently published in 1972) in which Emerson laid out the foundations of his theory of exchange, he formulated a model of the actor built on principles of behavioral analysis adopted from Skinner via Homans. Key concepts include reward (positive reinforcement), cost (rewards foregone), alternative exchange relations, dependence, and balance. Propositions are formulated based on the reinforcement notions of behavior first introduced into exchange theory by Homans and subsequently developed not only by Emerson, but also in the early work of Molm (e.g., Molm and Wiggins, 1979; Molm, 1980).

Emerson's Theory of Exchange Relations

A central focus of Emerson's theoretical framework is the exchange relation as the unit of analysis. As Turner (1986) notes, this move made exchange theory less vulnerable to charges of tautology and reductionism. Emerson's goal was to present a theory of the formation, maintenance, and termination of exchange relations and the forms of social structure created by connected exchange relations (e.g., networks of exchange). Less critical in this theoretical formulation is the precise nature of the values of the actors involved or the cognitive structure of their interests. Assuming actors enter exchange relations for reasons of reward (or avoidance of negative reinforcement in alternative relations), the focus shifts to understanding aspects of the exchange relations and the structure of the networks or groups in which they are embedded. The emphasis on the social relation as the unit of analysis distinguishes Emerson's work from that of Homans and Blau and allowed Emerson to present a more coherent theory of social structure.

Power and Dependence in Exchange

The primary legacy of Emerson's work on social exchange is his conception of how power is determined by the dependence of one actor on another in an exchange relation and how dependence is structured by the nature of the connections among actors in networks of exchange opportunities that deny or provide access to exchange alternatives. The key definition of power in Emerson's formulation is: The power of actor A over actor B in the Ax:By exchange relation (where x and y represent resources of value) increases as a function of the value of y to A, and decreases proportional to the degree of availability of y to A from alternative sources (other than B). These two factors (resource value and availability) determine the level of B's dependence on A and thus A's power over B. That is, the power of A over B is a direct function of B's dependence on A in the A:B exchange relation. The more dependent B is on A, the more power A has over B. Embedding this relationship in a network of exchange opportunities creates the basis for a structural theory of power in exchange networks.

Exchange relations are connected to the extent that exchange in one relation affects or is affected by the nature of the exchange in another relation. The connection according to Emerson's work can either be positive or negative. A negative connection means that exchange in one relation reduces the amount or frequency of exchange in another exchange relation involving one of the same parties (e.g., the A–B and B–C exchange relations are negatively connected at B if exchange in the A–B relation reduces the frequency or amount of exchange in the B–C relation). A connection is positive if the amount or frequency of exchange in one relation increases the amount or frequency of exchange in an exchange relation involving at least one of the parties to both exchanges (e.g., the A–B relation is positively connected to the B–C relation if exchange in the A–B relation increases the frequency or amount of exchange in the B–C relation). These are modal cases; however, exchange in two relations may also be 'mixed,' involving both positive and negative exchange connections relating to different aspects (or dimensions) of exchange. Exchange in more complicated networks may involve both positive and negative connections (see Cook et al., 1983), often with different actors in the network of exchange relations. In addition, one form of exchange can be mixed with or embedded in networks in which exchanges of another type are dominant (see Molm et al., 2012).

Exchange Networks

Emerson (1972, 1976) (Cook and Emerson, 1978) expanded this important direction of development in exchange theory in later publications formulating what is now known as 'exchange network theory.' Markovsky et al. (1988) subsequently developed a similar perspective they called 'network exchange theory' (also referred to as 'exchange-resistance theory,' Heckathorn, 1983). This latter approach derives from Willer's (e.g., Willer and Anderson, 1981; Willer, 1999) 'elementary theory' of social relations, which has an affinity with exchange concepts, but is not derived from Emerson's power-dependence perspective. These traditions of work in recent research have much in common, despite the remaining subtle differences in assumptions about actor behavior, network connections, and bases of power. In all of these programs of research the main focus of the early empirical work was determining the structural determinants of the distribution of power in networks of varying configurations.

Early debates about the value of exchange theory in the social sciences were centered on the role of rationality, tautology, and reductionism (see Emerson, 1976). These debates gave way during the 1980s and 1990s to more sophisticated arguments in the field concerning theoretical strategy and the best ways to

develop microlevel models of exchange that inform macro-level processes. More complex theoretical formulations emerged during this period based on the results of careful empirical work, much of it experimental, testing the fundamental propositions derived from exchange theory. Emerson's formulation provided the impetus for much of this empirical work primarily because he formalized the theory to make it more precise and therefore testable. Subsequent formulations adopted a similar theoretical strategy (e.g., Markovsky et al., 1988; Bonacich, 1998; Bienenstock and Bonacich, 1992, 1993; Friedkin, 1992; Skvoretz and Willer, 1993; Whitmeyer, 1994; Yamaguchi, 1996; and, more recently, van Assen, 2003, and van Assen and van de Rijt, 2007, among others).

Key Assumptions of Exchange Theory

The key assumptions of exchange theory summarized by Molm (1997), (see also Molm and Cook, 1995: p. 210) include the following: (1) behavior is motivated by the desire to increase gain and to avoid loss (or to increase outcomes that are positively valued and to decrease outcomes that are negatively valued); (2) exchange relations develop in structures of mutual dependence (both parties have some reason to engage in exchange to obtain resources of value or there would be no need to form an exchange relation); (3) actors engage in recurrent, mutually contingent exchanges with specific partners over time (i.e., they are not engaged in simple one-shot transactions); and (4) valued outcomes obey the economic law of diminishing marginal utility (or the psychological principle of satiation). Based on these core assumptions, various predictions are made about the behavior of actors engaged in exchange and the effects of different factors on the outcomes of exchange. The power-dependence principle, in addition, allows for the formulation of predictions concerning the effects of increasing the value of the resources involved in the exchange and the availability of resources from alternate sources.

Power Inequalities in Networks

Empirical work since the 1980s established several primary facts about exchange in networks of social relations. Power inequalities in networks of exchange are determined by access to valued resources in the network. The networks structure this access by providing connections or links to certain actors and restricting access to others. The structure of the network determines the accessibility of resources and thus the nature of the distribution of power in the network (see e.g., Cook and Emerson, 1978; Cook et al., 1983; Markovsky et al., 1988; Whitmeyer, 1999; Yamagishi et al., 1988). Subsequent empirical work has extended this research, developing a number of new formalizations concerning the structure and size of the networks, the form of exchange, and the dynamic nature of the processes involved over time (e.g., Cook and Yamagishi, 1992; Markovsky, 1987, 1995; Markovsky et. al., 1993; Skvoretz and Lovaglia, 1995; Willer, 1992; Willer and Skvoretz, 1997). For example, van Assen (2003) examines a large number of networks up to size nine and demonstrates that power-dependence theory and exchange-resistance theory make similar predictions regarding the classification of the types of power exercised. Similarly, van Assen and van de Rijt (2007) analyze dynamic exchange networks, investigating the effects of adding and deleting links in the network over time on the payoffs to the actors involved and their 'neighbors.' Willer et al. (2012) have also begun exploring more general analytic procedures for extending exchange network theories to apply to large-scale networks.

In exchange relations characterized by power inequalities, the use of power clearly varies not only by network structure and size but it also varies depending on whether the actors control positive or negative outcomes. Extending the theory to deal with the exercise of coercive power within social exchange relations, Molm (1997) produced insights into the nature of power relations in situations in which the actors have not only reward power, but also punishment power. Comparing the behavioral effects of the use of different bases of power in social exchange relations, Molm demonstrated that the results that hold for the exercise of reward power do not hold for the use of punishment. Specifically, punishment power is used much less frequently, in part because it carries with it the risk of withdrawal from the relationship on the part of the target of the punishment to the extent that the relationship can be exited. (Molm focused primarily on voluntary exchange relations; that is, both parties have some degree of control over their involvement in the exchange and can exit if they so desire.) However, when punishment power is used it tends to be very effective in modifying behavior to make the relations more mutually rewarding in the long run. According to Molm (1997: p. 268): "When punishment is administered contingently and consistently, coercion is a powerful means of getting what one wants." However, coercive power is rarely used due to the risks involved.

Coercive Power

Integrating the analysis of coercive power with reward power in social exchange relations allowed for the investigation of a wider range of social situations in which more complex exchanges occur. Frequently, those involved in ongoing exchange relations have control over both rewards and punishments (even if it is only the withholding of rewarding behaviors). In addition, Molm's (1997) work made a major contribution to the analysis of the strategic use of structurally based power advantages and disadvantages. As she correctly noted, the missing link in Emerson's (1962, 1972) original work on power-dependence relations was the nature of the precise mechanisms that relate structural determinants of power with the actual use of power by those in positions of power. In this effort norms of fairness or justice and attitudes toward risk play a key role. Conceptions of fairness constrain the use of power under some conditions especially the use of coercive power, and aversion to risk makes some actors unwilling to use the structural power at their disposal for fear of loss. Fairness also affects the extent to which actors get committed to one another over time in exchange relations that differ in the degree of risk and uncertainty involved.

Risk and Uncertainty

Additional empirical research was subsequently conducted that extended the existing exchange theories to deal with the effects of

important factors such as uncertainty and risk on the nature and structure of social exchange. Facing uncertain environments, actors involved in exchange are more likely to seek to form committed exchange relations (Cook and Emerson, 1978; Kollock, 1994; Lawler and Yoon, 1996). Commitment reduces the extent to which actors seek exchange with alternatives and thus serves to reduce the power inequalities both within the exchange relation and within the network in which the relation is embedded. As Kollock's (1994) work demonstrated, uncertainty not only results in commitment formation as a means of reducing uncertainty, it also tends to be correlated with perceptions of trustworthiness of the actors involved in the exchange relations.

Yamagishi et al. (1998) reported that trust emerges in exchange relations under conditions of high uncertainty as actors form commitments to exclusive exchange with one another in an attempt to avoid the possibility of exploitation by unknown actors who enter the exchange opportunity structure. Under conditions of low uncertainty, actors are much more likely to continue to 'play the market' and to avoid forming commitments to specific partners in order to maximize their access to valued resources. (Uncertainty in these experimental studies referred to the likelihood of being exploited by a new partner in an exchange network of opportunities that changes over time. In Kollock's (1994) study, the uncertainty involved concerned the quality of the goods to be exchanged.) In research on trust, uncertainty and vulnerability are often defined as two of the key elements of situations in which trust considerations are paramount (e.g., Heimer, 2001; Cook, 2005; Cook et al., 2004). As Molm's recent work (e.g., Molm et al., 2009) demonstrates, different types of exchange vary in the nature and extent of the uncertainty and risk involved, which in turn affects the degree of trust that emerges. Reciprocal exchange, for example, typically results in greater trust than does negotiated exchange with binding agreements. It also results in more resilient, affective trust, and greater cohesiveness (Molm, 2010).

Relational Cohesion and Social Exchange

Lawler and his collaborators (e.g., Lawler and Yoon, 1993) developed a theory of relational cohesion based on principles of social exchange. This work examined the conditions under which social exchange relations develop out of opportunities for exchange and are linked to the emergence of positive emotions about the exchange relation. These positive emotions and subsequently feelings of cohesion or solidarity, Lawler argues, develop based on positive evaluations of the outcomes of the exchanges between actors and the frequency of their exchange. Low frequency and unfavorable (or less favorable) exchanges are much less likely to lead to commitment to the relation, to positive feelings about the exchange, and to feelings of cohesiveness or solidarity (i.e., what Lawler terms a 'we-feeling'). This line of research returned to some of the earlier anthropological work that examines the links between exchange and solidarity in social relations. It also integrated into existing theoretical conceptions of exchange theory important considerations of the emotional bases of exchange and commitment (see Lawler and Yoon, 1998; Lawler and Thye, 1999).

Building on his theory of relational cohesion and his affect theory of social exchange (Lawler, 2002), Lawler and his collaborators (e.g., Lawler et al., 2008) have explained how various types of exchange (reciprocal, negotiated, generalized, and productive) result in different levels of 'microsocial order,' reflecting the nature of the recurrent social interactions, emotional responses, perceptions of being a group, and affective sentiments directed at the group or network and subsequent attachment to the group. These are the elements of social order as it emerges at the microinteractional level. It is strongest when activities are joint (as is the case with productive exchange) and when the tasks involved generate a shared sense of responsibility (strongest in productive exchange and weakest in generalized exchange). The significance of this work is that it connects exchange theories explicitly to the broader study of social commitments (Lawler, 2009) and social order.

Applications of the Theory

Applications of exchange theory and power-dependence concepts extend from dyadic relations like dating and longer-term relationships including marriage (e.g., Sprecher and Metts, 1999) to often short-term relations characteristic of various practitioner–client interactions (such as physician–patient meetings under managed care, see Grembowski et al., 1998), in addition to more macro-level applications. The focus of analysis at the microlevel is often the nature of the relationship and the factors that predict satisfaction (or dissatisfaction) and longevity (or termination) of the relation. Two dimensions frequently investigated in this respect are the degree of power imbalance in the relationship and the extent to which the relationship is embedded in a network of other important exchange relationships. Power imbalance in partnerships often creates additional tension in the relation as actors try to manage the resource differences between the parties to the exchange and attempt to maintain commitments in the face of alternatives. Within an organizational structure such as that produced under managed care in the health care delivery system, choice of provider is often limited exacerbating patient concerns with their dependence on the available physicians. Mechanisms are put into place to provide patients in these settings access to redress if the power of the physician is abused. These include increased professional and utilization reviews by colleagues, administrators, and those who insure the patients. In all cases in which a power imbalance exists in an exchange relation there is the potential for exploitation, thus widely differing mechanisms have been created that serve to provide some monitoring to insure the equitable and fair treatment of those who are most dependent and thus vulnerable to the abuse of power. A prime example is the oversight demanded frequently in nursing homes that must deliver care to one of the most dependent populations in the USA, the infirm aged. Aspects of both power-dependence theory and exchange theory have proven useful in the study of power processes in many contexts, as well as in the analysis of trust and its breakdown, especially in organizations with the

potential for power abuse (e.g., those characterized by hierarchy, unequal power relations, and a lack of transparency or monitoring of those in power).

At the more macrolevel, exchange networks represent an important framework for analyzing the global transformation of corporate relations mediated by the Internet, as well as the reorganization of the workplace and the exponential increase over the past decade in interpersonal connections over the Internet (e.g., Facebook, Linked-In). The world of global business has been transformed as B2B (business to business) commerce has become a dominant mode of conducting transactions at the macrolevel. In addition, business to client (B2C) relations and P2P (peer to peer) connections have grown steadily creating a world-wide market not only for goods and services, but also for the recirculation and recycling of objects in second-hand markets. These relations represent complex networks of exchange and trade that include not only economic, but also political and social dimensions of transnational significance. For example, networks that link actors with common cause have been at the core of recent political transformations especially in the emerging democracies in various regions of the world. Future research will likely see the further expansion of exchange analyses of power and influence in global networks embedded in complex social and political realities, as well as new studies of exchange in what is now referred to as the 'sharing economy,' emerging forms of broad-based generalized exchange systems mediated by the Internet such as TaskRabbit, CouchSurfing, AirBnB, Uber, RelayRides, and FreeCycle.

Executive Functions during Childhood, Development of

Sanja Šimleša and Maja Cepanec, University of Zagreb, Zagreb, Croatia

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Executive functions (EFs) encompass higher order processes required for purposeful, goal-oriented activity. The processes most frequently included in this term are inhibition, working memory, cognitive flexibility, and planning. More recent studies show that EF processes have different developmental trajectories and start their intensive development at different periods. This article presents definitions of EF, changes in the concept and studies of EF during time, different development trajectories of EF and related changes in the brain through three developmental periods: (1) infants and toddlers, (2) early childhood, and (3) middle childhood, and finally methodological issues in the studies of EF in children.

Definitions of Executive Functions

Executive functions (EFs) play an important role in the individual's development, from language development, imaginative play and theory of mind in childhood, academic success in adolescence, to career and family planning and organization in young adulthood. Any alterations in the development of EFs, due to biological or environmental factors, reflect on the individual's social, academic, and professional development and social status. Although authors define the concept of EFs in different ways, they all agree that EFs encompass higher order processes required for purposeful, goal-oriented activity and adaptive responses to novel or complex situations (Anderson, 2002). In general, the processes most frequently mentioned in the literature are response inhibition, working memory, cognitive flexibility, and planning. According to some authors, this group also includes temporal organization of behavior, goal anticipation, activity initiation, activity monitoring, and response evaluation.

Changes in the Focus or Emphasis over Time

Changes in the Concept of EF (Unitary vs. Nonunitary Concept of EF)

In the early studies, EFs were viewed as a homogenous construct, i.e., a unitary, central EF rather than a number of different processes encompassed by the same term. More recent studies define EFs as an encompassing term including a whole range of interrelated processes required for a purposeful, goal-oriented behavior. This is evidenced by a number of findings from various disciplines: (1) from the clinical point of view, patients rarely suffer from a general executive dysfunction; (2) processes encompassed by the term EFs are localized in different areas of the prefrontal cortex; (3) measures of different aspects of EFs show low correlations; (4) factor analyses point to the existence of more factors; and (5) different processes of EFs have different developmental trajectories.

In their attempt to answer the question whether EFs form a unitary construct or encompass different, isolated processes, Miyake et al. (2000) found that correlations between different tasks that assess inhibition, cognitive set shifting, and working memory ranged from 0.4 to 0.6. Such relatively high correlations indicate that these are different constructs that partially share the common basis. The basis of these moderately high correlations according to some authors is inhibitory control, according to others it is working memory, and according to a more complex approach it is both inhibitory control and working memory.

Changes in the Studies of EF over Time

Until recently, EFs were exclusively studied in the frame of adult neuropsychology because it was believed that the frontal lobe remains 'functionally silent' until adolescence, which is why the tasks intended for EF assessment were appropriate for adults only. This led to neglecting of the research on developmental changes in the domain of EFs. According to the Scopus database, the first studies on EFs appeared in the 1970s, and from 1980s to 2000s there was an increase in the number of studies on EFs in children. While in the first half of the 1980s, there was only a single study on EFs that included the term 'children,' in the 1990s the share of such studies considerably increased, to as much as 22% from 1996 to 2010 (see Table 1).

With the increase in the number of studies, there also came advances in the methodological approach. Methodological advances brought about new findings on the maturation of the central nervous system and related cognitive development. Some of the EF aspects were at first intensively researched in animals, in order to experimentally examine the relationship

Table 1 Results from the Scoups database showing the number of studies with the keyword 'executive functions' (EFs), the number of studies with the keywords 'executive functions' and 'children,' and their ratio between 1981 and 2010

	Number of studies		*Percentage studies of EF involving keyword 'children'*
Years	*'EF'*	*'EF' & 'children'*	
1981–1985	14	1	7.1
1986–1990	25	3	12.0
1991–1995	154	22	14.3
1996–2000	847	188	22.2

Figure 1 Increase in the number of studies (according to the Scopus database) on executive functions in clinical populations of persons with defined developmental disorders and/or syndromes according to the year of study.

between behavior (behavioral measures of EFs) and the structure and function of the central nervous system (especially in the prefrontal cortex). These were the studies that set the basis for modern developmental research on EFs, which closely relates behavioral and neurophysiological indicators.

Today, EFs start to be tested very early, mostly at the age of 7 months, and EFs' development can be followed until adult age. Simultaneous to the 'discovery' of the developmental aspect of EFs began the research on EFs in developmental disorders (Figure 1), especially in the population of children with attention-deficit/hyperactivity disorder, autism spectrum disorders, and language disorders/impairments. As expected, there were fewer studies on EFs in developmental disabilities that had a more clearly defined etiological mechanism (genetic and metabolic disorders).

Developmental approach to EF research showed that considerable changes in these abilities took place during childhood, which can be greatly attributed to the maturation of the central nervous system. Therefore, the development of EFs has also been extensively studied in children born preterm, showing the influence of immature or vulnerable nervous system on the development of higher developmental functions.

Development of Executive Functions

Different processes encompassed by the name 'executive functions' have different developmental trajectories and begin their intensive development and maturation at different time points. Welsh et al. (1991), by using different measures of EFs, tested children aged 3–12 years and found evidence of a staged development – some components of EFs start to mature earlier and others later. However, most of the studies show that the greatest changes in the performance on tasks that assess EFs are observed in early childhood. Significant changes in the abilities of EFs that take place in preschool age are associated with increasingly better behavioral self-control in children, and lead to the shift from external to internal mechanisms (resources) of self-regulatory behavior.

However, since the task complexity and the mode of EFs testing is different in the infant, preschool, and school period, a careful interpretation is required when making comparative analyses and studying the developmental trajectories of some EFs. In other words, it is impossible to test a certain function throughout the entire developmental period with the same test/task, and even if this is done, the mechanisms of task solving and the child's relying on different cognitive processes that are emerging or have already been acquired hinder interpretation and decrease the data reliability.

Development of EF in Infants and Toddlers (0–2 Years)

According to the research available so far, behaviorally measurable EF abilities begin to appear in the second half of the first year of life. Studies of EFs in infants and toddlers are mostly oriented to studying inhibitory control and working memory.

For investigation of cognitive development in children of that age, most authors use Piaget's research techniques, i.e.,

Figure 2 A-not-B task.

object permanence paradigm and object retrieval task. The most frequently used task for assessing early EFs is the A-not-B task (a variant of delayed response task), in which the child searches for an object that the experimenter has hidden in front of him or her in one of the two holes (Figure 2). After the child repeatedly finds the object in the hole A, the experimenter hides it in hole B. If the child continues to search for the object in the previous place (hole A), he or she makes the A-not-B error. The experimenter slowly increases the delay between hiding and searching. Piaget (1954) observed, which was later confirmed by most of the other researchers, that children aged 7–12 months make the A-not-B error, but in this period great differences are observed in the delay length required for the A-not-B error to occur (Diamond, 2002).

Piaget believed that the A-not-B error was not caused by the child's failure to remember, but by his or her inability to distinguish between the object and the location where it had first been found. Over the years, many different explanations have been given as to what mechanisms lead to making of the A-not-B error. There are controversial opinions regarding the validity of the task but it has to be pointed out that similar controversies have also been encountered, to a lesser or greater extent, in other tasks for EF assessment in all age groups (see Chapter 4 on methodological problems in EFs assessment).

In an attempt to determine the factors that influence the performance on the A-not-B task, researchers designed a number of task variants and varied the position and posture of the child, number of holes, the degree of the object's visibility, the mode of response making (looking vs. reaching), the cover color, etc. A contribution to answering the question which resources are needed for a successful task performance was also made by neuroscientific research. Diamond and Goldman-Rakic (1989) showed in a study on rhesus monkeys that the A-not-B error was made by adult monkeys with frontal lobe lesion, but not by those with either parietal lobe lesions or hippocampal lesions (Diamond et al., 1989). The fact that neither parietal nor hippocampal lesions led to making of the A-not-B error speaks in favor of the fact that a successful performance on this task is a result of a combination of abilities, i.e., it depends on the ability of maintenance of an object representation in memory (during the delay) and the inhibition of incorrect response(s), which are the functions of the frontal cortex.

As expected, further research showed a substantial and clear association between the performance on delayed response tasks and functioning of the dorsolateral prefrontal cortex. Therefore, Diamond (2002) says that "This is one of the strongest brain–behavior relations in all of cognitive neuroscience" (p. 468). Due to such a strong relation between the successful performance on tasks that assess EFs and functioning of prefrontal cerebral cortex (PFC) and PFC networks (*see* Cognitive Control (Executive Function): Role of Prefrontal Cortex), it is almost impossible to talk about EF development without taking into consideration the maturation changes in the central nervous system. As already mentioned, the frontal cortex was earlier considered to be functionally silent in childhood, which is why EFs were not studied in this period. However, more recent research in the field of neuroscience has shown that the first two years of life are a period when substantial and important processes of brain maturation and reorganization take place. At the end of the first year of life, when the first important changes in the performance on the A-not-B task can be behaviorally observed, other great structural and functional changes take place in the prefrontal cortex. It is the time when intensive processes of postnatal reorganization of cerebral cortex occur, which include the growth and maturation of pyramidal ('cognitive') neurons, formation of the basic cytoarchitectural characteristics of the prefrontal cortex, morphological differentiation of neurons (growth and formation of dendritic and axon branches), synaptogenesis (formation of neuronal connections), axon myelination, etc. Functionally, in the period of 6–12 months postnatally, an increase in glucose metabolism in the prefrontal cortex takes place, as well as an increase in the density of dopamine receptors, which is considered to be particularly important for the development of higher cognitive functions.

The A-not-B task has in many behavioral and neuroscientific studies served as a basis for EF research, both in children and in other primates. Some studies used it in a slightly changed form to assess other aspects of EFs, i.e., cognitive flexibility. The

Figure 3 Day-night task.

starting point of such studies was the studying of perseveration, which according to some authors was a reflection of immature or partially developing skills.

Besides delayed response tasks, EF studies, especially those on planning in infants, use the object retrieval task (Diamond, 1981), in which the child can reach a goal only by creating an effective plan. In this task, the target object is placed inside a glass box and can be reached only if the child finds out which side of the box is open. If we take into consideration that the target object is visible the whole time, this task does not require short-term memory but good planning skills and self-control. It has been shown that in 6.5- to 7-month-old children the performance is fully guided by visual input, while in 11- to 12-month-old children it is planned. This implies that planned, purposeful, goal-oriented behaviors are already present in 12-month-old children, and that these abilities get substantially improved at the end of the first year.

EF development during the second year of life has been considerably less studied, especially because there are no widely accepted and used tasks for assessing EFs in that age group. McGuigan and Núñez (2006) experimentally examined executive functioning in 18- to 24-month-old children by using novel detour reaching tasks that included novel-causal and novel-arbitrary sequences. In this way, they controlled the saturation of the tasks by the demands of working memory and inhibitory control. The success of the task performance and the mechanism analysis of EF development were based on changing the task's complexity by varying the number of steps the child has to make to solve the task, the number of attention shifts, etc. Authors believe that early changes in top–down systems at the end of the second year of life may bring about key changes in complex executive functioning that will crystallize in the preschool year.

The progress in the working memory abilities, inhibitory control, and planning is also reflected in the area of self-regulation. The second year brings the development of the basic ability of self-control that includes postponement of the child's own demands as well as the beginning of behavioral regulation. Active regulation of behavior and emotions at the end of the second year is a good predictor of some aspects of social development.

Development of EF in Early Childhood (2–6 Years)

Preschool age is a period of intensive cognitive development. In children aged 3–6 years, progress is clearly visible in many aspects of EFs: inhibitory control, working memory, cognitive flexibility, and simple planning. Understanding of EFs in early childhood is also important because of their relation to the language development and theory of mind, which together play an important role in the social development of an individual.

In this age group, inhibition is most frequently assessed with Stroop-like tasks, such as day–night task (Gerstadt et al., 1994) and grass–snow task (Carlson and Moses, 2001), which test the verbal response ability. In the day–night task, the children are required to say 'day' when they see a picture of stars and moon, and to say 'night' when they see a picture of the sun, over 16 trials (Figure 3). In the grass–snow task the children are required to show a white color patch when the experimenter says 'grass' and a green color patch in response to the word 'snow' over 16 trials. Like the adult Stroop test, children have to (1) maintain the task instructions over a series of trials, (2) suppress a dominant response associated with a perceptual stimulus, while (3) selecting and executing a competing, conflicting subdominant response. Children aged 3–4 years often find it difficult to solve these tasks, while children older than 5 years solve these tasks easily (have more correct answers with less latency).

At the age of 5 years, the ability to retain and manipulate complex information, i.e., working memory, starts to develop increasingly and reaches a plateau in early adulthood. It is believed that in this age, working memory starts to divide into verbal and visuospatial working memory (Alloway et al., 2004), which clearly corresponds to the terms 'phonological loop' and 'visuospatial sketchpad' in Baddeley's model of working memory. The most frequently used task for working memory assessment in this age group is digit span task (Davis and Pratt, 1995). In this task, the experimenter shows the child a doll that repeats the experimenter's words backwards. If the experimenter says 'one, two' the doll repeats 'two, one,' and the experimenter asks the child to repeat the numbers backwards, like the doll. The experimenter begins with two numbers, adding more numbers until the child makes a mistake three times in a row. Children aged 3 and 4 years mostly have difficulties in completing this task, while children aged 5 years repeat two or three numbers backwards.

In order to test the combined action of working memory and inhibition, Luria (1966) developed the tapping task (Luria's tapping task) in which the child is required to tap the surface twice when the experimenter taps once, i.e., taps once when the experimenter taps twice. In this task, the child has

Figure 4 The dimensional change card sort.

to keep in mind two rules and inhibit the natural tendency to imitate the experimenter. The greatest progress in this task has been made in the age group 3–4 years, and the greatest progress in the response speed between 4.5 and 5 years.

Besides the development of the abilities of inhibition and working memory, the preschool age is the age of intensive development of cognitive flexibility. The most frequently used task for assessing cognitive flexibility in preschool age is the Dimensional Change Card Sort (DCCS) (Figure 4) (Frye et al., 1995). The child is shown a card with pictures of different shapes in different colors and is asked to sort the cards according to one dimension (e.g., shape), and after that according to another (e.g., color). This task tests the child's ability to switch the cognitive set. According to the authors of this task, most 3-year-olds can sort the cards according to one dimension, but experience difficulties when the instructions change. Most 4- to 5-year-old children do not experience difficulties with the cognitive set switch, i.e., they complete this task successfully.

At the end of early childhood, the planning ability improves and reaches a plateau in early adulthood. Many researchers believe that improvement in the planning ability is a consequence of the improvement in the ability of response inhibition and working memory. According to Senn et al. (2004), tasks for assessing inhibition and working memory explain 29% variance of planning tasks in children aged 2–6 years. The tasks frequently used for assessing the planning ability are Tower of London (TOL) (Shallice, 1982) and Tower of Hanoi (TOH) (Simon, 1975), in which the child is asked, on the basis of a model, to put three balls of different colors in a set configuration on three pegs of different heights. The two tasks are almost the same. They both require transferring of objects (balls or disk) on pegs from an initial start state to a goal end state in a minimum number of moves. Furthermore, both tasks impose some common rules restricting the manner in which the objects can be moved from peg to peg. Only one ball/disk can be moved at a time, and any ball/disk not being moved must remain on the peg. The difference between these two tasks is that in the TOH task, the minimum number of moves required for each trial is not specified, whereas in TOL, participants are instructed to achieve the configuration in a specified minimum number of moves for each trial, as quickly as possible. Also, the goal model in the TOH task is presented as a physical model, while in the TOL task it is presented pictorially. The TOL and TOH are useful as a measure of EF in children because the procedure offers a variety of difficulty levels. While solving this task, the participant goes through different processes: the initial state, or the state in which the problem solver sorts out the given objects; the goal state, or the solution state that the problem solver tries to achieve; and the steps that the problem solver takes to transform the initial state into the goal state, which initially may not be obvious. Research showed age-related improvements in TOL performance, as older children are more accurate and make fewer extra moves when solving TOL problems.

In conclusion, many behavioral studies showed considerable developmental changes in the performance on many tasks that assess the processes of EFs in early childhood. However, very little is known about the structural and chemical changes in the central nervous system that underlie these behavioral changes. Nevertheless, research points out that in this period the number of dendritic spines (the parts of pyramidal neurons' dendrites that contain the most of synapses) is still much higher than that in the adult brain. The fact is that a large number of synapses is created postnatally (much more than in the adult brain) and is later decreased over time (synaptic pruning) so that only those 'survive' that have been proved to be needed by experience or

active use. It seems that such 'excessive' number of synapses (which remains in the prefrontal cortex for an especially long period) creates an anatomical substrate for neural plasticity and some types of learning, and enables considerable changes in the way the brain processes information and in the development of higher cognitive functions.

Development of EF in Middle Childhood (6–12 Years)

Although in the last few years EF research has been oriented to early childhood, it is exceptionally important to examine EFs during middle childhood. Examining EFs through the entire childhood, even the entire lifetime, can help us more easily answer the question whether EF is a unitary construct, how the relationship between certain aspects of EFs changes developmentally, and what influence EFs have on school performance, social functioning, and emotional control.

Although early childhood brings intensive fundamental changes in the ability of prepotent response inhibition, middle childhood brings greater changes in the response speed and accuracy. In this period, inhibition is most frequently tested by computerized tasks, because they can precisely measure behavior variables (e.g., reaction time). In these tasks, the child is required to respond to certain stimuli presented on the computer screen while inhibiting the response to distracter stimuli. The results mostly show that 8-year-old children make fewer errors caused by inattention, impulsivity, and distractibility than children aged 10–12 years, i.e., during middle childhood this aspect of EF undergoes considerable maturation.

In children aged 6–12 years, the progress is also clearly visible in the abilities of working memory, cognitive flexibility (particularly flexible shifting from old to a new cognitive set and back), and planning, and especially in the increase in response speed. The abilities of working memory and cognitive flexibility appear to emerge in the preschool years, but linear progress is clearly visible only in middle childhood (e.g., on tasks for assessment of working memory, linear progress was observed between 4 and 15 years of age). Here, we have to have in mind that age-related changes in performance depend on the complexity of a particular task.

Cognitive flexibility in middle childhood is most frequently assessed by the Wisconsin Card Sorting Test (WCST). Compared to the DCCS task, this task requires children to find the correct sorting principle by themselves. In its conventional form (Heaton, 1981), the WCST consists of 4 key cards and 128 response cards with geometric figures that vary according to three perceptual dimensions (color, form, or number). The child is required to find the correct sorting principle by trial and error and with the help of examiner feedback. When the child 'discovers' the correct sorting principle, he or she has to maintain this sorting principle across changing stimulus conditions while ignoring the other, irrelevant, stimulus dimensions. After 10 correct responses in a row, the classification principle changes without warning. Using this task, some researchers showed that children aged 6–10 years demonstrated considerable performance improvements, but only when they reach the age of 13–15 years the performance equals that of adults (Welsh et al., 1991).

The EF that shows the largest gains in middle childhood is planning. Planning refers to the ability to formulate actions in advance and to approach a task in an organized, strategic, and efficient manner, which is precisely why this activity is a critical part of goal-oriented behavior. Tasks that are used for EFs assessing are the TOL (Shallice, 1982) and TOH (Simon, 1975) (for task description, see the article on early childhood). Executive planning and problem-solving abilities have been shown to be more advanced in older than in younger children, both in terms of the number of errors and the task-solving time. The time variables show age-related changes, with younger children (7–9 years) solving the task more slowly and having longer total problem-solving times than older children (10–12 years). However, Luciana and Nelson (2002) used the computer version of the TOL (Cambridge Neuropsychological Testing Automated Battery (CANTAB)) to compare a sample of healthy 4- to 12-year-olds with college students and reported that 12-year-olds did not reach young adult levels in terms of perfect solutions and the number of moves required to complete five-move problems.

In general, the understanding of typical EF development in middle childhood is important because the start of school brings a number of changes into the child's life – social environment is changed, expectations from the child are higher, and the complexity of everyday experiences is greater. The studies that aimed to determine the causality between EFs and school functioning have been inconclusive. However, they have found an association between EFs and social–emotional development (social and emotional self-regulation, effortful control, and the ability to resist temptation) as well as school success in math, reading, and writing.

In summary, we can say that middle childhood is the period of dynamic behavioral, cognitive, and emotional development. Anatomically, elimination of excessive synapses in the prefrontal cortex has still not been terminated. At the age of 7 years, neural density is a bit higher than the average value in adults, and even at the age of 11 years children have more synapses than adults (Huttenlocher, 1979). At the age of 9–10 years, the glucose mechanism level starts to decrease, and the adult level is reached at the age of 16–18 years (Chugani, 1994). Functionally, a large number of abilities that are under the responsibility of the frontal lobe have an extended development period.

In conclusion, in middle childhood and adolescence, progress is visible in the abilities of cognitive flexibility and planning, as well as response speed. Although the specifics of the developmental trajectory depend both on the complexity of the task and the scoring method, it seems that inhibition shows prominent improvement during preschool age and less changes later on, and that planning ability experiences the greatest maturation changes. Although the developmental pace is slower, changes in performance (especially in response speed) can be followed up to early adult age.

Methodological Issues in Studies on EF in Children

EF studies face various conceptual problems and challenges. The most important conceptual problem is the synonymous use of terms such as 'executive,' 'control,' 'frontal functions,' and 'control system,' which have not unambiguously operationalized.

A considerable methodological problem is the lack of solid evidence on the validity and reliability of the tasks used for EF assessment. In the assessment of EFs, researchers encounter two types of 'errors.' One is related to the multifactorial nature of executive tasks so it is not quite clear which aspects of EFs they measure (e.g., most of the tasks that measure inhibitory control also measure working memory), or at least to what extent the success on a certain task is influenced by a certain aspect of EFs. The second type of 'error' is related to the fact that the task performance can depend not only on EFs but also on other abilities and other levels of information processing and response making. Therefore, a successful performance on such tasks might include the processes of visual perception, motor skills, processing speed, etc. For all these reasons, poor task performance can be a consequence of EF impairment, or can have a secondary cause in the impairment of some other function.

A further challenge that researchers face is the issue of ecological validity. In an attempt to capture certain narrow segments of EFs, sometimes very simple single tasks are used that do not pick up EF deficits that a person may have in real life, where much more complex demands are present. For example, persons with frontal lobe damage have shown good performance on EF tests, but they are still impulsive and disorganized in real life. One of the ways to solve this problem, especially in children, is to broaden the nature of EF assessments by introducing parent questionnaires designed to index children's everyday EF skills.

It is important to point out that the assessment of EFs in early age mostly includes specifically designed but nonstandardized tasks. Even today there are only a few standardized instruments for assessing EFs in children, e.g., computerized test CANTAB and Attention and Executive Functions domain in a Neuropsychological Assessment-II, to name only some. The lack of standardized tests did not for a long time allow researchers to identify individual differences and detect deviations in the development of EFs, as well as to follow their developmental trajectories by longitudinal research.

Researchers face different methodological problems depending on whether their field of study is EFs in children or in adults (Hughes and Graham, 2002). Compared to adults, EF assessment in infants and children is to a different extent burdened by certain methodological problems, both conceptual and technical in nature.

One of the problems in the assessment of EFs in adults is the difficulty to distinguish between the use of automatic processes and the use of controlled processes during task solving. This distinction is not absolute, so it is better to describe it in terms of a continuum. The processes required to perform an unfamiliar task gradually change from controlled to automatic and even small changes in the task demands can cause the shift. This all leads to an inability to distinguish between executive and nonexecutive tasks. Also, when an 'executive' task is repeated, one cannot be sure whether its underlying processes stay the same, i.e., there is a weak test–retest reliability in adults. The difficulty in distinguishing between automatic and controlled processes is also present in the assessment of children, but it has a somewhat lesser influence. The fact is that children can perceive a novel and unfamiliar task as novel and unfamiliar for a longer period of time. Theoretically, only novel tasks can pick up deficits of EFs, so the corresponding validity and test–retest reliabilities are usually greater in EF assessment in children.

Although the complexity of standard 'executive' tasks is a problem in EF assessment in adults, in children this problem is less obvious, since the tasks, in order to be developmentally appropriate, are simpler, which reduces the influence of a number of different underlying processes.

However, researchers of EFs in children face other challenges, which are less pronounced in the assessment of adults, such as the problem of motivation and the influence of language abilities on the final performance. For example, inadequate understanding of verbal instructions for task solving, i.e., inadequate understanding of language, can influence the performance on EF tasks. Many tasks for assessing EFs in adults are inappropriate for children (e.g., Stroop word test) precisely because of inadequate language understanding.

Some methodological problems encountered in the assessment of children are technical in nature. For example, computerized tests that are conducted using touch screen are mostly considered very reliable and allow precise following of respondent's responses; however, in children, the screen sometimes is not sensitive enough to register the child's pressure or hand temperature (Luciana and Nelson, 2002). This is why all the results expressed as response latency in young children have to be considered with caution.

Due to all the listed factors that can influence the final score on the EF assessment tasks in children, in the analysis and interpretation of the results it is advisable to consider both quantitative (e.g., percent correct, time taken) and qualitative (e.g., frequency of rule violations, displays of frustration or of distractibility) measures of the performance. The fact is that in most EF assessment tasks, performance is evaluated as the sum of all accurately solved tasks. In this way, the total final quantitative result is affected by a range of both executive and nonexecutive abilities. The control of such factors, i.e., at least those that are reflected in the child's behavior and that are visible to the experimenter, could contribute to a better interpretation of the obtained results.

Finally, it is important to point out that in the last 20 years, possibly the greatest progress in the research of EFs, besides methodological progress in terms of computerized tests application, has been made in the integration of behavioral and neuroscience perspectives, which has led to a better recognition of the interactions between social and biological influences on the development of EFs in children.
